The questionnaires which were designed for gathering the data for this dissertation could be refined. As has been suggested above certain items did not contribute much to their categories or were not worded well enough to measure what was intended. What has been learned about the effectiveness of the questionnaires as a measuring tool for the study of mysticism could be incorporated into a revised version. For multiple sessions a questionnaire would be needed which could show an increase each time in a particular item if it occurred. During the first session, for example, the participant might rate certainty of the encounter with ultimate reality as "5" on a 0-5 scale if this were the strongest experience he had ever had or had imagined possible up to that time. In his next session, however, he might experience an even more "ultimate" reality. Therefore, although the same questionnaire might be used, a 0-7 scale would provide the opportunity to indicate the same strength as previously ("5"), a little stronger ("6"), or very much stronger ("7"). For the third session a 0-9 scale could be used, etc. New types of questionnaires could also be tried. Instead of directly asking about categories by means of individual scattered items, each category could be explained in an instruction manual similar to that written for the judges. Then each category could be scored as a whole or by a cluster of the most representative items for that category. Another approach might be to quote short descriptions which are good examples of each category from the writings of the mystics and ask the participant to compare his drug experience with these examples on a rating scale of degree of similarity.

Another modification in any on-going research in this field would be longer and more thorough follow-up studies. The subjects could be checked periodically for one to three years to assess possible psychological benefit or harm. For accurate assessment of persisting changes in attitude and behavior, not only the person's own subjective judgment but also those of other persons close to him, such as spouse or intimate friend, could be measured. Actual changes in behavior could be listed and tabulated.

---

[1] Chwelos and Blewett found this to be the case with LSD (*Handbook*, pp. 66-67).

If the conclusions of this dissertation are first confirmed and clarified by the additional experiments suggested above, other experiments could be designed to test more precisely the effect of set and setting on the relative frequency of occurrence of specific mystical elements in the drug experience. For example, if a relatively homogeneous sample of subjects were divided into four equal groups (two groups of experimentals and two of controls), four sessions could be run for each group in two different settings by two different groups of investigators in a Latin-square design. The "religious" setting could be in a chapel as described above by investigators convinced that the drug experience was positive and even potentially "mystical". The other setting would be in a psychiatric hospital by investigators convinced that the experience was negative and merely a "model psychosis." The same pre-drug tests, questionnaires, and interviews would be given to each group, but the initial set and setting in two groups would be "religious" and in two, "psychiatric."

Each group would have two drug sessions and two control sessions - one of each in each of the two settings. The same questionnaire which would have both "positive" and "negative" responses would be given to each group after each session after an account had been written by each person. It would be interesting to determine whether or not the initial set and setting had a controlling effect on both the initial and subsequent experiences in different and the same settings. Such a series of experiments might also shed light on the whole problem of the relationship between psychosis and intense mystical states of consciousness. All the accounts could be content analyzed for both "mystical" and "psychotic" elements.

The study of the basic phenomenology of mysticism in the drug experiences of persons already interested in religion would be only the first step. The claim of some investigators[2] that mystical phenomena occur even in persons with no interest in religion could be checked by administering psilocybin in a setting free from any religious suggestion. Of course, the basic setting factor of trust, confidence, and friendliness should be maintained.

Let us turn now to the second kind of research which would involve experimental investigation of possible social application in a religious context. Such experiments would be undertaken only after adequate evidence had been accumulated by means of the first or theoretical approach to substantiate the findings and suggestions of our research. If it were confirmed, for example, that personally and socially useful changes in behavior are produced with a meaningful religious setting and preparation, experiments could be designed to develop the best methods and conditions of administration to provide the maximal chance for beneficial effects to occur without danger.

One such experiment could be to establish a retreat center with a trained, permanent staff consisting of psychiatrists, clinical psychologists, and ministers. A uniform technique of procedure and testing would have to be devised so that the results over a period of time could be compared. Small groups, preferably already in rapport, of laymen or ministers to whom such a setting would be meaningful would spend from five to seven days at the center. Screening by means of physical examination and history, psychological testing, preparation of an autobiography, and preliminary interviews, would be done before the group came to the retreat center. Several leaders (staff personnel) would join each group as integral members for the duration of the retreat. At least the first three days would be spent in preparation for the drug session and would include readings of selected materials which had been found helpful to others, group discussions with the staff, worship and meditation alone and with the group, meals and recreation as a group, and individual interviews with the staff. The emphasis would be on building group rapport, a spirit of trust and friendship, and serious expectation of a meaningful experience. The techniques which have proved successful in group dynamics work could be used to facilitate sharing of past experiences between group members and to build the interpersonal honesty and solidarity of the group. After this period of preparation, one whole day would be set aside for the drug session in an appropriate religious setting. The staff members with whom the groups had been working would be in charge with assistance if needed from other staff members who would be standing by. Group discussion of the experience would be an important part of the retreat and would continue for at least two days after the session while data was gathered by the staff by means of written accounts, questionnaires, and interviews. Follow-up meetings of the group could be arranged, and perhaps a repeat of the retreat could be made after a year.

---

[2] Leary and Clard, *op. cit.*, pp. 252-253. See also Sherwood, Stolaroff, and Harman, *J. Neuropsychiatry*, Vol. IV, No. 2, pp. 76-79. The loose use of the terms "religious experience" or "classic, mystic, conversion reaction." adds confusion and misunderstanding unless these terms are carefully defined. See our discussion above on this point, pp. 24-27.

Another experiment along a similar line would be the formation of small natural groups of 4-6 people who would meet periodically for serious religious and personal discussions in depth, Bible study, and worship in the form of prayer and meditation. After a period of several months in which rapport, mutual trust, and bond of fellowship were being established, a drug session could be planned in collaboration with a psychiatrist and minister who both had been trained in the use of psychedelic substances. Pretesting could be done at one of the meetings. A whole day would have to be set aside for the session with the psychiatrist and minister in attendance to administer the drugs, run the session, and collect data in such a way as to add to positive set and setting. Post-session discussion, meetings, and collection of follow-up data would also be important here. The effects of multiple drug sessions could also be studied.

In both of these proposals the most practical kind of controls could be matched groups who underwent the same retreat or cell-group experience without the drug over the same time interval with the same staff at the same place, but at a different time from the experimentals. Once the effectiveness of the method was proved in terms of personal and social usefulness, the most valuable data would consist of comparisons between groups in which different techniques were tried to determine the best method to use for an experience of of maximal benefit.

It must, however, be emphasized that much more research needs to be done at the theoretical level before such pilot research projects for social application should be attempted. Such work must be done carefully and cautiously both because of the social resistance to be overcome and because of potential dangers involved.

In our society the use of drugs for any reason other than for a medical indication in the treatment of some specific illness is suspect. Fear of addiction or physical harm is the intuitive association, but beyond this legitimate fear perhaps the American Puritan heritage with its disapproval of pleasure or enjoyment for its own sake, especially if unearned by hard work, may be a factor. Also the relative ease with which the phenomena of the mystical state of consciousness were induced in our experimental subjects with the aid of psilocybin might seem undeserved when compared to the rigorous discipline which many mystics describe as necessary. Although a drug experience might seem "unearned", our evidence has suggested that preparation and expectation play an important part, not only in the type of experience attained, but in later fruits for life. Perhaps the hardest "work" comes after the experience which itself may only provide the motivation for future efforts to integrate and appreciate what has been learned. The best way to overcome social resistance is to demonstrate the value and safety by careful and responsible investigation.

Although our experimental results indicated predominantly positive and beneficial subjective effects, possible dangers must not be underestimated and should be thoroughly evaluated by specific research designed to discover the causes and methods of prevention of physical or psychological harm, both short term and long term. While physiological addiction has not been reported with psychedelic substances, psychological dependence might be expected if the experience were continually repeated. The intense subjective pleasure and enjoyment of the experience for its own sake could lead to escapism and withdrawal from the world. An experience which is capable of changing motivation and values might cut the nerve of achievement. Widespread apathy toward productive work and accomplishment could cripple a society. Another possible danger might be prolonged psychosis or suicide in very unstable or depressed individuals who were not ready for the intense emotional discharge. If it can be determined that any of these forms of harm occur in certain types of individuals, research could be directed toward the development of pre-test methods to screen out such persons. Our evidence would suggest that research on conditions and methods of administration of the drugs might minimize the chance of harmful reactions. Spectacular immediate advance must be sacrificed for ultimate progress by careful, yet daring and imaginative research under adequate supervision.

The ethical implications also cannot be ignored. Any research which uses human volunteers must examine its motives and methods to make certain that human beings are not being manipulated like objects for purposes which they do not understand or share. But in research with powerful mental chemicals which may influence the most cherished human functions and values, the ethical problem is even more acute. The mystical experience historically has filled man with wondrous awe and has been able to change his style of life and values, but it must not be assumed that greater control of such powerful phenomena will automatically result in wise and constructive use. Potential abuse is just as likely. Those who undertake such research carry a heavy responsibility. A detailed examination and discussion of all the ethical implications would require another thesis; such considerations must be constantly kept in mind as a reminder of the more than normal caution required.

This is not to say that research should be stopped because of the fear of these various risks in an extremely complex and challenging area with great promise for the psychology of religion. But while research is progressing on the theoretical or primary level and before projects for testing useful social application in a religious context become widespread, serious and thoughtful examination of the sociological, ethical, and theological implications is needed without delay.

Appendix A

MEDICAL HISTORY FORM FOR VOLUNTEER SUBJECTS FOR PSILOCYBIN RESEARCH[1]

Name: ....

Address: ....
....

Date: ....

Age: ....

Sex: ....

I. Have you ever had any of the following:

Heart disease (rheumatic heart disease, congenital heart defects, or high blood pressure) Yes No

Epilepsy Yes No

Liver disease Yes No

Previous jaundice Yes No

If you have answered "yes" to any of the above, please explain below:

....
....
....

II. a) How much alcohol do you consume per week on the average? ....

b) How often do you use aspirins and in how large a dose? ....

c) What other headache or sleeping pills do you use, how often? ....

d) How much tobacco do you use per week on the average? ....

III. a) Have you ever received psychotherapy? Yes No

When? ....

For how long? ....

Are you presently in therapy? ....

b) Have you ever been hospitalized for mental illness? Yes No

If yes, please explain in detail (symptoms, length and number of hospitalizations, treatment).

....
....
....

c) Has anyone in your immediate family ever been hospitalized for mental illness? Yes No

If yes, who and for what?

....
....
....

IV. Have you any allergic reactions (thorazine, etc.)? Yes No

If yes, please explain:

....
....
....

Examined by: .... M.D. Date: ....

---

1. This was given about three weeks before the experiment and reviewed during physical exam at first interview.

Appendix B

PRE-DRUG EXPERIENCE QUESTIONNAIRE[2]

1. Name:	1. ....
2. Address:	2. ....
3. Phone:	3. ....
4. Age:	4. ....
5. Sex:	5. ....
6. Religious denomination:	6. ....
7. Present occupation:	7. ....
8. Future plans:	8. ....
9. Have you ever had a drug experience with psilocybin, mescaline, or LSD?	9. ....
10. Family history: indicate ages of brothers: Sisters: Which parents are alive?	10. ....
11. Are you single? married? divorced?	11. ....
12. Where you raised in the church?	12. ....
13. At what age did you join the church?	13. ....
14. Did you ever attend a young peoples' church camp? At what age?	14. ....
15. Which of your parents were actively interested in religious?	15. ....
16. Which of your parents actively participated in the church?	16. ....
17. Do you hesitate to call yourself a Christian?	17. ....
18. Indicate your theological position on the following continuum:	18. Orthodox Neo-orthodox Liberal
19. How meaningful is the usual worship of your public religious life to you?	19. unmeaningful, slightly meaningful, very meaningful sometimes, very meaningful usually
20. How meaningful is your participation in Holy Communion?	20. unmeaningful, slightly meaningful, very meaningful sometimes, very meaningful usually
21. Are you undertaking your life work in the religious sense of a vocation or calling?	21. ....
22. Was your decision to follow your life work tied to any particular experience you have had? If so, describe briefly:	22. ....
23. Did you ever have a sudden conversion experience? At what age? A more gradual one? Over how long? Climax at what age?	23. ....
24. Have you ever had any mystical or religious experience in the presence of nature? If so, describe briefly:	24. ....

25. Have you ever had an experience in which you felt that you transcended time and/or space? (If yes, circle which) Describe briefly:	25. ....
26. Have you ever had an intuitive experience of a sense of Presence of the Divine? If so, describe briefly:	26. ....
27. Have you ever experienced a feeling of mystical union to any degree? If so, describe briefly:	27. ....
28. Have you ever had an experience in which you felt that the Numinous was made near to you? If so, describe briefly:	28. ....
29. Have any of your religious experiences given you a feeling of joy, blessedness, or peace in the Biblical sense of the peace that passes all understanding? Have you had this experience in ways or circumstances that you would not consider religious?	29. ....
30. Do you practice any spiritual exercises such as prayer? regular meditation? yogic exercises? special postures? breath control? fasting? others? (describe):	30. ....
31. Do you have a regular prayer life besides formal public worship?	31. ....
32. Do you practice intercessory prayer? prayers of thanksgiving? prayers of petition? requests for forgiveness?	32. ....
33. Do you believe that the effects of prayer are completely auto- or group suggestion?	33. ....
34. Have you ever experienced a sense of sin in a general sense? In a specific sense in which you felt overpoweringly guilty about a particular wrong deed or attitude?	34. ....

---

2. This was administered about three weeks before the experiment and reviewed during first interview.

Appendix C

POST-DRUG QUESTIONNAIRE WITH SIGNIFICANCE LEVELS OF THE DIFFERENCE BETWEEN SCORES OF EXPERIMENTALS AND CONTROLS[3]

(*Interactive version of this questionnaire is here:* http://en.psilosophy.info/TripograM.)

Name: ....   Date: ....

Approximately what percentage of the 2-1/2 hour service did you remain in the chapel?

Please evaluate the following items in regard to your own experience in the psilocybin experiment. Rate each descriptive unit according to the following scale:
0 - did not experience at all
1 - cannot decide whether I experienced this or not
2 - experienced slightly
3 - experienced moderately
4 - experienced strongly

Note: Please reserve the highest rating (4) for a qualitative level which would equal or excel any previous personal experience or expectation which you would consider **strong** of these states. Feel free to make any further comments on any item in order to clarify your response.

1. Seeing symbolic meanings of things.	....	(.18)
2. Feeling of unity with your group.	....	(.64)
3. Sense of the preciousness of life.	....	.02
4. Feeling of being very wise, knowing everything.	....	(.23)
5. Terror or fear.	....	.004
6. Sense of finitude.	....	(.23)
7. Sense of wonder.	....	.004
8. Panic.	....	.016
9. Lose of self.	....	.001
10. Easy understanding of the feelings of others.	....	(.5)
11. Concern and preoccupation with other people coming and leaving the room.	....	(.64)
12. Being able to operate on several levels at once.	....	.004
13. Sense of humility.	....	(.35)
14. Sense of well being.	....	(.38)
15. Fear of losing control.	....	.004
16. Seeing a light which appeared to have no naturally explainable source.	....	.016
17. Feeling that you were going to die during the experience.	....	(.63)
18. Sense of having known the universe in its wholeness.	....	(.016)
19. General sense of sin.	....	(.5)
20. Conviction of certain specific sins in your life.	....	(.50)
21. Sense of forgiveness or cleansing.	....	(.35)
22. Sense of loneliness or aloneness.	....	.02
23. Sense of ultimate goodness as the basis of reality.	....	.035
24. Intuitive knowledge of your immortality.	....	(.11)
25. Sense of judgment on your life.	....	(.78)
26. Appearance of various levels of consciousness.	....	.001
27. Suddenness of appearance of various levels of consciousness.	....	.002
28. Suddenness of disappearance of various levels of consciousness.	....	.004
29. Stability of level of consciousness during the experience.	....	.035

30. Transciency of duration of deepest levels.	....	.002
31. Transciency of duration of levels other that the deepest.	....	.004
32. Permanence of new levels of consciousness **after** the experience.	....	(.062)
33. Sense of certainty or conviction of encounter with ultimate reality (in the sense of being able to "know" and "see" what is really **real**) at the time of the experience.	....	.020
34. Sense of certainty or conviction of encounter with ultimate reality now (in looking back).	....	(.062)
35. Sense that what was encountered was **not** real at the time of the experience.	....	(.5)
36. Sense that what was encountered was **not** real **now** (in looking back).	....	(.5)
37. Intensity of the response to ultimate reality.	....	.004
38. Totality of the response to ultimate reality.	....	.016
39. Exaltation.	....	.020
40. Depression.	....	(.09)
41. Love.	....	.035
42. Hate.	....	(.35)
43. Tenderness.	....	(.66)
44. Exuberance.	....	.002
45. Meanness.	....	(.19)
46. Insecurity.	....	(.11)
47. Blessedness.	....	(.15)
48. Despair.	....	.02
49. Peace.	....	(.09)
50. Overflowing energy.	....	.008
51. Anxiety.	....	(.26)
52. Ecstatic Joy.	....	.004
53. Intellectual illumination.	....	(.062)
54. Retention of such illumination after the experience.	....	.008
55. Sense of being grasped and dealt with.	....	.004
56. Sense of awe or awesomeness.	....	.011
57. Sense of reverence.	....	(.78)
58. Sense of mysterious fascination in spite of terror or fear (in the sense of a shaking or trembling in the utmost depths of your inner being).	....	.008
59. Sense of the wholly otherness of what was met in the experience.	....	.035
60. Sense of your own finitude in contrast to the infinite.	....	(.09)
61. Sense of profound humility before the majesty of what was felt to be sacred or holy.	....	(.062)
62. Sense of presence of what was felt to be holy, sacred, or divine.	....	(.64)
63. Sense of absence of anything that was felt to be holy, sacred, or divine.	....	(.35)
64. Sense that the experience is describable by logical statements which are not contradictory.	....	(.35)
65. Sense that an attempt to describe the experience in logical statements becomes involved in contradictory language.	....	.016
66. Sense that the experience cannot adequately be described in words.	....	.008
67. Sense that what is experienced forms part of a larger whole.	....	(.26)
68. Paradoxical dissolving of the subject-object dichotomy in spite of the empirical multiplicity of objects (they are still perceived as separate).	....	.008
69. Intuitive experience of the essences of objects.	....	.016
70. Sense of unity with these objects.	....	.008
71. Felt awareness of the life or living presence in all things.	....	.032
72. Paradoxical transcendence of space as defined in 68-71.	....	.004
72a. Sense of the loss of the multiplicity of all particular sense impressions.	....	.004
73. Pure awareness with no empirical distinctions (i.e., one is beyond the self consciousness of sense impressions, yet one is not unconscious).	....	.002
74. Sense of unity with ultimate reality at the level described by 72a and 73.	....	.008
75. Transcendence of time in the sense defined by 72a-74.	....	.002
76. Transcendence of space in the sense defined by 72a-74.	....	.004
77. Consciousness of a "Beyond" or "More".	....	(.15)
78. Expansion of usual personal consciousness to other dimensions **within** the self.	....	.001

79. Expansion of usual personal consciousness to other dimensions **beyond** the self.	....	.004
80. Transcendence of time in the sense defined by 77-79.	....	.001
81. Transcendence of space in the sense defined by 77-79.	....	.004
82. Sense of the presence of God.	....	(.83)
83. Contact or bond with God.	....	(.64)

Please rate yourself on the following items both a) **during** and b) **since** the experience:

		During		**Since**
84. Increased integration of personality.	....	(.37)	....	(.09)
85. Disintegration or destructive effects on personality.	....	(.062)	....	(.13)
86. New significance to life.	....	(.62)	....	.002
87. Lessening of significance to life.	....	(.13)	....	(1)
88. Death experience.	....	.032	....	(.063)
89. Rebirth experience.	....	.032	....	(.19)
90. Feeling of love toward others.	....	(.38)	....	(.38)
91. Feelings of antagonism and hate toward others.	....	(.09)	....	(.25)
92. Felt need for some type of service for others.	....	(.50)	....	(.25)
93. Actual changes in behavior in ways you would consider constructive and positive.	....	(.66)	....	(.18)
94. Sense of increased self-centeredness.	....	(.11)	....	(.25)
95. Conversion experience.	....	(.35)	....	(.19)
96. Sense of belonging to a new and greater unity.	....	.008	....	(.062)
97. Sense of subjective delusion.	....	(.063)	....	(.063)
98. Confusion of thinking.	....	.004	....	.032
99. Feelings of unreality.	....	.016	....	(.063)
100. Physical discomfort.	....	(.23)	....	(1)
101. Loss of memory for part of the experience.	....	.35	....	.020

Please rate the following phenomena in regard to your experience **during** the experiment:

102. Loss of consciousness.	....	.16
103. Distortion of visual perception.	....	(.055)
104. Colors more intense.	....	.001
105. Visions of colors, geometric patterns, objects, animals, people, scenes (circle any experienced).	....	.001
106. Seeing colors around heads or bodies of others.	....	.032
107. Hearing voices which were not from anyone present or from the loudspeaker.	....	(.13)
108. Unusual odors or scents.	....	(.063)
109. Hunger.	....	(.15 - for controls)
110. Tears.	....	(.35)
111. Sense of body melting.	....	(.19)
112. Nausea.	....	.008
113. Dizziness.	....	(.15)
114. Sensation of floating.	....	(.09)
115. Sense of bodily warmth.	....	.035 (for controls)
116. Itching or burning of skin.	....	.011 (for controls)
117. Headache.	....	.5 (for controls)
118. Coldness.	....	(.37)
119. Sense of being out of the body.	....	(.062)
120. Explosive anger of fury.	....	(.13)

121. Anxious about having to come "out of it."	…………	.008
122. Did you particularly like or feel close to either of your leaders? Which one? Please rate your feeling (0-4).	…………	(.11)
123. Did you particularly dislike either leader? Which one? Please rate your feeling (0-4).	…………	.032
124. Did you particularly like or feel close to any participant in the experiment? Who? Please rate your feeling (0-4).	…………	(.35)
125. Did you particularly dislike any participant in the experiment? Who? Please rate your feeling (0-4).	…………	(.37)

Please rate (0-4) the degree to which you now feel that:

126. Your experience was valuable to you personally.	…………	(.062)
127. Your experience was mystical or religious.	…………	(.062)
128. Do you think you had psilocybin?	…………	.001
129. Please rate (0-4) the meaningfulness of the service as a whole.	…………	(.64)

---

3. Probabilities that the difference was due to chance are listed for each item. The Sign Test was used and the prediction was made that the scores of experimentals would be higher than of controls unless otherwise indicated.

Appendix D
FOLLOW-UP QUESTIONNAIRE WITH SIGNIFICANCE LEVELS OF THE DIFFERENCE BETWEEN SCORES OF EXPERIMENTALS AND CONTROLS[4]

Name: .... Date: ....

SECTION I:
Please list the most important persisting changes in you since Good Friday. These changes should be only those which you feel are due to your Good Friday experience and which are still present in you now.

Then please make a numerical evaluation of the benefit or harm of each change with the following rating scale. Use for comparison your status before Good Friday.

5 - **Very** strongly beneficial (to a degree more than ever before in my life and stronger than 4 for this type of change)
4 - Strongly beneficial (to a degree equivalent to any previous change or expectations of this type)
3 - Moderately beneficial
2 - Slightly beneficial
1 - Cannot decide whether this was beneficial or not
0 - None: neither beneficial nor harmful
-1 - Cannot decide whether this was harmful or not
-2 - Slightly harmful
-3 - Moderately harmful
-4 - Strongly harmful (to a degree equivalent to any previous change of expectation of this type)
-5 - **Very** strongly harmful (to a degree more than ever before in my life and stronger than 4 for this type of change)

Please list your changes below:[5] (Use the back of the sheet if needed.)
....
....
....
....
....
....
....
....
....
....
....
....
....
....
....
....

---

[4] Probabilities that the difference was due to chance are listed for each item. The Sign Test was used and the prediction was made that the scores of experimentals would be higher that of controls unless otherwise indicated.
[5] These changes were content analyzed by the judges with the accounts written soon after the Good Friday experience.

Name: .... Date: ....

SECTION II:

(*Interactive version of this questionnaire is here:* http://en.psilosophy.info/TripograM.)

Looking back on your Good Friday experience, please rate the **degree to which** at **any** time during that day (after the experience began) you experienced the following:

NOTE: In your evaluations of degree please use this rating scale:

5 - **Very** strongly (more than ever before in my life and stronger than 4)
4 - Strongly (would be equivalent in degree to any previous strong experience or expectation of this description)
3 - Moderately
2 - Slightly
1 - Cannot decide
0 - None, not at all

1. Loss of usual time sense.	....	.001
2. Loss of usual awareness of where you were.	....	.002
3. Certainty of the reality of what was experienced.	....	.020
4. Enhanced capacity of mind.	....	.008
5. Intensity of your response to the experience.	....	.001
6. Totality of your response to the experience.	....	.001
7. Sense of having known the universe in its wholeness.	....	.016
8. Definite change in your usual state of consciousness.	....	.002
9. Suddenness of appearance of various dimensions of consciousness.	....	.020
10. Intellectual illumination.	....	.035
11. Ecstasy.	....	.004
12. Peace.	....	(.5)
13. Happiness.	....	(.23)
14. Sense of presence of what can only be described as nameless.	....	.032
15. Sense of sacredness with which you regarded your experience.	....	(.37)
16. Feeling that you could not do justice to your experience by a verbal description.	....	.001
17. Certainty of encounter with ultimate reality (in the sense of being able to "know" and "see" what is really real).	....	.008
18. Loss of your own identity.	....	.004
19. Pure awareness beyond any empirical content.	....	.002
20. Meaningfulness of your own life.	....	(.055)
21. Rebirth experience.	....	.016
22. Awe.	....	.011
23. Communion with ultimate reality.	....	(.23)
24. Deep interpersonal relations with other people present.	....	.035
25. Loss of feelings of difference from objects.	....	.016
26. Eternity.	....	.002
27. Gain of insightful knowledge experienced at an intuitive level.	....	.004
28. Love (toward one's fellow man as a human being, not of an erotic or sexual nature).	....	(.26)
29. Delight.	....	.016
30. Sense of your own finitude in contrast with the infinite.	....	.020
31. Expansion of usual personal consciousness to other dimensions **within** the self.	....	.001
32. Expansion of usual personal consciousness to other dimensions **beyond** the self.	....	.004
33. Fusion of the self into a larger undifferentiated whole.	....	.008
34. Spacelessness.	....	.004
35. Timelessness.	....	.004
36. Feeling of completeness.	....	.004
37. Intuitive experience of the essences of objects.	....	.032
38. Sense of being grasped and dealt with by the experience.	....	.001
39. Joy.	....	.016
40. Sense of reverence.	....	(.5)

41. Sense of belonging to a new and greater unity.	....	.008
42. Loss of sense of self as a predominantly positive experience.	....	.004
43. Loss of sense of self as a predominantly negative experience.	....	.004
44. Sense of unity with objects.	....	.032
45. Blessedness.	....	(.11)
46. Exaltation.	....	(.37)
47. Freedom from the limitations of the self in connection with a unity or bond with what was felt to be all-encompassing and greater-than-self.	....	.004
48. Sense of being at a spiritual height.	....	.016
49. Unity with ultimate reality.	....	.016
50. Sense of the presence of God.	....	(.5)
51. Love of God or Christ.	....	(.26)
52. Return to your usual state of consciousness the day after the experience.	....	.002

SECTION III:

(*Interactive version of this questionnaire is here:* http://en.psilosophy.info/TripograM.)

The purpose of this section is to measure certain persisting effects which you consider due to your Good Friday experience. Use for comparison your status before Good Friday. Using the same rating scale as in Section II preceding (singe 0 to 5 scale), please evaluate in regard to your **present** condition **the degree to which**:

53. The experience has changed your philosophy of life.	......	a) positively .001	......	b) negatively (1)
54. You have become more sensitive.	......	a) more sensitive .002	......	b) less sensitive (1)
55. You have less personal integration.	......	a) (.5)	......	b) more .002
56. You have learned something useful from the experience.	......	a) .004	......	b) detrimental (1)
57. You have had difficulty in trying to communicate your own experience to others who were not present.	......	a) .002	......	b) Have had ease (.11 - for controls)
58. Your behavior has changed in ways you would consider negative since the experience.	......	a) (.13)	......	b) positive (.002)
59. You now feel a greater need for service for others.	......	a) .035	......	b) lesser need (1)
60. You are less your true self with others.	......	a) (1)	......	b) more .008
61. Feelings of depression have increased.	......	a) (.063)	......	b) decreased (.063)
62. Your appreciation for life has.	......	a) increased .002	......	b) decreased (.25)
63. You have a greater sense of inner authority in your life.	......	a) .002	......	b) lesser (1)
64. Your life has a diminished dynamic quality.	......	a) (.25)	......	b) heightened .008
65. Others have remarked about a negative change in you since Good Friday.	......	a) (1)	......	b) positive change (.19)
66. You have decreased feelings of happiness.	......	a) (.13)	......	b) increased (.11)
67. Your life has more meaning.	......	a) .035	......	b) less meaning (.5)
68. You are more tolerant toward others.	......	a) .032	......	b) less tolerant (1)
69. You have less peace in your life.	......	a) (.7)	......	b) more peace (.11)
70. You are convinced now in retrospect that you encountered ultimate reality in your experience (i.e., that you "knew" and "saw" what was really **real**).	......	.016	-	-
71. You have a decreased achievement efficiency.	......	a) (.7)	......	b) increased (.5)
72. You have an increased sense of reverence.	......	a) (.062)	......	b) decreased (1)
73. You have been accused of logical contradiction in trying to describe the meaningfulness of your own experience to others who were not present.	......	(1)	-	-

74. Feelings of anxiety have increased.	......	a) .032	......	b) decreased .016
75. You now have a less certain vocational commitment.	......	a) (1)	......	b) more certain (.063)
76. You have a more positive relationship with others.	......	a) (.063)	......	b) more negative (.9)
77. You are a less creative person.	......	a) (.25)	......	b) more creative (.06)
78. You have more enthusiasm for life in general.	......	a) (.062)	......	b) less enthusiasm (.25)
79. Your sense of values (i.e., what is important to you in life has changed.	......	a) positively .035	......	b) negatively (1)
80. You place more importance on traditional theological formulations to express spiritual insights.	......	a) (.5)	......	b) less importance (.035)
81. Your life has less richness.	......	a) (1)	......	b) more richness .020
82. You feel that you now know a new dimension of life.	......	a) .004	-	-
83. You spend less time for devotional life.	......	a) (.6)	......	b) more time .008
84. Your appreciation for the whole of creation has increased.	......	a) (.035)	......	b) decreased (.25)
85. You now feel more hatred toward others.	......	a) (.9)	......	b) more love .016
86. You have lost by now the state of consciousness which you experienced on Good Friday.	......	a) .004	......	b) retained (.5)
87. You have more joy in your life.	......	a) .016	......	b) less joy (.25)
88. You now feel that what you experienced was a subjective delusion.	......	(.25)	-	-
89. Time spent in quiet meditation has increased.	......	a) .008	......	b) decreased (.5)
90. You have less of a sense of the preciousness of life.	......	a) (1)	......	b) more .008
91. You are a more authentic person.	......	a) .016	......	b) less authentic (1)
92. You now feel that the meaningfulness of your own experience is beyond words.	......	.004	-	-
93. You have less of a sense of the adventurous outreach of life.	......	a) (1)	......	b) more (.09)
94. Your experience has been valuable for your life.	......	a) .020	......	b) has been a hindrance (.13)
95. You now feel that life has taken a definite change of course because of this experience.	......	.032	-	-
96. You have tried to recapture any parts of the Good Friday experience since then.	......	(.15)	-	-
97. You have been successful in this attempt.	......	(.19)	-	-
98. You would be interested in repeating the same experience you had on Good Friday.	......	a) (.26)	......	b) would not be interested (.5)
99. You would be interested in having more of these kind of experience (not necessarily with the hope of an exact repetition of your Good Friday experience).	......	a) (.23)	......	b) would not be interested (.25)
100. You are convinced that you had psilocybin.	......	a) .001	......	b) did not .001 (for controls)

Appendix E
CONTENT ANALYSIS

Content Analysis Instruction Manual for Judges

1. On the basis of categories described below, you are asked to score twenty accounts of personal experiences.
The scoring is based on the degree to which each category is experienced.
The degree is defined in terms of either intensity or completeness, depending on the nature of the category. In general, the following rating-scale is used:
3 Experienced to a **strong** degree. (Such a level corresponds to the highest degree of intensity or completeness as defined for each category.)
2 Experienced to a **moderate** degree. (More than slight, but not enough to be scored as strong.)
1 Experienced to a **slight** degree. (But enough for inclusion in this category.)
0 None, or not applicable. (The account gives no impression that this category was experienced at all.)

2. Definition and Explanation of Categories to be Scored

I. **Transcendence of Time and Space**
This category refers to loss of the usual sense of time and space, without loss of consciousness (in contrast to sleep or coma). Time means clock time, but may also be one's personal sense of his past, present, and future. Subjectively-felt time may be shortened or lengthened. Space means the usual three-dimensional perception of one's environment.

Loss of time and space is scored separately, and is based on completeness. A high score (3) for time indicates that for some period, however be belief, the experiencer is aware that his normal sense of time is completely gone. There may be a feeling of being completely "outside" of time, or that time has "stopped" or ceased to exist. Lesser degrees than "complete" are the shortening or lengthening of subjective periods of time. The apparent lengthening or dragging of time which may be described in connection with boredom is the lowest level (1). A strong degree of loss of the sense of space indicates that the experiencer is no longer aware of where he is during the experience. There may be a complete or partial feeling of loss of the limitations of usual three-dimensional space. If orientation remains but spatial perceptions are altered, score as "slight" (1) or "moderate" (2), depending on the degree of approximation to complete loss of space. Experience of "eternity" or "infinity" indicates timelessness, spacelessness, or both, depending on the context.

II. **Positive mood**
The elements of this positive mood are joy, love, and peace. They are called positive because of the value attached to them by the experiencer. They may occur together or individually, and at any time during the whole experience - e.g., at a climactic point or as part of an afterglow effect.

Joy may be of the exuberant or quiet type and may include such feelings as exaltation, rapture, ecstasy, bliss, delight, and/or happiness. Love is of one's fellow man as a human being, but not of an erotically stimulation nature; or may be of a cosmic scope such as love of nature, of the universe, of God. A feeling of harmoniousness may be included.

Scoring level is based on intensity:
3 This level indicates an experience that is profound and deeply felt, i.e., close to the strongest human experience of such elements. For example, the strongest degree of peace is that which "passeth understanding." Tears associated with any of these elements of positive mood may be a sign of the overpowering nature of the experience.
2 This level lacks the extreme profundity and depth of feeling, but the mood is still moderately intense.
1 There is definite evidence here of the mood being present, but with low intensity.

III. **Sense of Sacredness**

This category comprises the sense of sacredness which is evoked by the experience, in whole or in part. The sacred is here defined broadly as that which a person feels to be of special value and capable of being profaned. The basic characteristic of sacredness is a non-rational, intuitive response in the presence of inspiring realities. No religious "beliefs" need necessarily be involved in such a sense of sacredness or be included in a sense of reverence or a feeling that what is experienced is holy or divine.

This basic characteristic may be described directly, or the response may take various forms. The experiencer may be moved with awe, wonder, humility, or a hushed reverent feeling. Spontaneous acts such as prayer or kneeling may be evoked. Other examples of this non-rational, intuitive response may include a sense of: finitude in contrast to the infinite; humility before the overpowering majesty of that which uniquely transcends the finite; the "wholly other"-ness of what is felt to be holy or divine; a mysterious fascination in spite of a feeling of awe, fear, or terror in the sense of shaking or trembling in the innermost depths of one's being; the urgency or energy of the holy or divine. As indicated, fear or terror may be part of the experience of sacredness, but certainly also can be experienced in a quite unrelated way. Do not score fear under this category, if not related.

The use of religious terminology to describe the experience is another indication of sacredness. For example, the response may be interpreted by the experiencer as a sense of Divine Presence, the consciousness of a Beyond or More, the awareness of some cosmic Principle or Universal Self, or more specifically as the presence of Christ, God, or some other deity. Sacredness may be strongly felt, however, without any of these interpretations being give.

Feelings of joy, love, or peace (of the previous category) may be evoked with a response of sacredness. Such an interconnection of these two categories should be watched for, but both categories should only be scored when there is clear indication that elements of both are present. However, they do not necessarily occur together.

Scoring level is based on intensity of the basic response in any of the possible forms. Intensity may be judged from the tone, manner of description, and context.

3 The profound sacredness of this level may include the high value and significance which the person places on his experience. The impact is shaking and very inspiring. Breathless awe may also accompany this level.
2 The profundity and extreme character of 3 is lacking, but the sacredness is still impressive.
1 Sacredness is definitely present, but weakly felt, i.e., not outstanding.

IV. **Unity**

The category of unity is divided into internal and external types which are different ways of experiencing an undifferentiated unity. The major difference is that the internal type finds unity through an "inner world" **within** the experiencer, and the external type finds unity through the external world **outside** the experiencer. Both types may be experienced by the same person.

A. Internal Unity

The essential elements of unity experienced by turning inward are: loss of usual sense impressions, and loss of self without becoming unconscious. The multiplicity of usual external and internal sense impressions (including time and space), and the empirical ego or usual sense of individuality, fade or melt away, while consciousness remains. In the most complete experience, this consciousness is a pure internal awareness beyond empirical content, with no external or internal distinctions. One is not unconscious, however, but rather very much aware of an "inner world" of undifferentiated unity.

These essential elements are described in terms of paradox. In spite of loss of sense impressions and dissolution of usual personal identity or self, the "I" still experiences the awareness of oneness or unity. The unity itself may be described as empty, yet full and complete. Either or both sides of this paradox may be emphasized by the various expressions used. On the one side, for example, the feeling of oneness with an empty unity expresses an awareness of the loss of sense impressions and may be indicated by such words as emptiness, void, abyss, wayless, unorganized, darkness, dissolution, or pure self. On the other side, the feeling of oneness with what is all-encompassing or greater than the usual self may be expressed by such words as fullness, completeness, pure being, or unity with the whole. These various expressions of the essential elements are evidence of the internal type of unity. Of course, the context must be considered.

Watch for associated experiences which may alert you to these essential elements. Some examples are: expansion of consciousness to another "world" of reality different from the ordinary; or consciousness of an underlying cosmic Principle, Beyond or More, Universal Self, Logos, Christ, or God. However, for internal unity to be scored, such experiences must have additional clear indication of the loss of sense impressions or self with retention of awareness (e.g., unity, bond, or absorption with the particular example or additional description with some of the expressions used above).

Scoring level is based on completeness:
3 A strong degree of completeness means that there is loss of the multiplicity of all sense impressions and complete loss of self. A pure awareness of an undifferentiated unity is present beyond empirical content with no internal or external distinctions. In fact, internal and external lose their meaning. Time and space are completely transcended.
2 A moderate degree of completeness means that internal distinctions remain. Although all external sense impressions and the usual sense of self are lost, internal imagery continues. Oneness is not complete.
1 There is definite evidence of the essential elements, but not in a complete a way as in level 2. Sense impressions are lost, but only partially. There is only incomplete loss of the sense of self. Some awareness of the external environment remains.

B. External Unity
In this sub-category, unity is perceived outwardly with the physical senses through the external world. A sense of underlying oneness is felt behind the empirical multiplicity. The observer or subject feels that the usual separation between himself and an external object (inanimate or animate) is no longer present in a basic sense, yet the subject still knows that his individuality is retained. In spite of the empirical multiplicity of objects, which are still perceived as separate, the subject-object dichotomy is nevertheless in a paradoxical sense dissolved. On one level, the objects are separate, yet on another they are, at the same time, one with the subject. Another way of expressing this same phenomenon is that the essences of objects are experienced intuitively and felt to be the same at the deepest level. The subject feels a sense of oneness with these objects, because he "sees" that at the most basic level all are a part of the same undifferentiated unity. This oneness may be felt through things or people. Such external unity may also come as a deeply felt awareness of the life or living presence in things. There may be the realization that nothing is "really dead".

Watch for associated elements such as expansion of consciousness beyond the usual sense of self or consciousness of a Beyond or More, some cosmic Principle, etc. Such associated elements may point to more specific evidence of oneness or unity through external things. Completeness of associated loss of time varies, but transcendence of space is only partial or paradoxical, because external objects seem both separate and yet not separate.

Scoring level is based on completeness:
3 At this most complete level, the oneness has both depth and breadth. The capsule statement, "All is One," emphasizes the broad dimension of this underlying unity in all things. A cosmic dimension i felt.
2 The depth of oneness through things or people is present, but not the same wide scope of underlying unity in everything as in the most complete experience. The loss of usual separation between subject and object is limited to the immediate rather than cosmic dimension.
1 Oneness, kinship, friendship is felt with unusual closeness, but the depth of oneness is not so complete as level 2.

V. **Transiency of Unity**
Transiency means non-permanence of duration, i.e., loss of the phenomena of internal or external unity after, or perhaps even before, the whole experience is over. The duration of unity during the experience may last from second to hours, and the completeness may vary. Disappearance may seem gradual because of the afterglow effect, but transiency means that unity is not continuously sustained when the experience

is over. Watch for indications that the essential elements are no longer present, e.g., mentions of "coming out" or "back to normal."

Scoring level is based on the intensity of the contrast between the degree of unity experienced during and afterwards:
3 A strong intensity of contrast means that although there may be a re-living in memory and persisting changes in other ways, the actual experience of unity does not continue in the ongoing life of the experiencer. Even a moderate or slight degree of unity can produce a strong contrast in comparison to usual consciousness.
2 A moderate intensity of contrast means that some of the actual phenomena of unity persist after the experience as a part of regular consciousness (even after 5 months), although perhaps in a lower degree of completeness.
1 A low intensity of contrast means that much of the actual phenomena of unity persists at the same level of completeness as during the experience as a part of regular consciousness.
0 No contrast means that the level of unity experienced continues unchanged afterwards. Of course, if none of the phenomena of unity was experienced at all, transiency also would be scored as 0.

VI. **Objectivity or Reality**
This category has two interrelated elements: (1) insightful knowledge or illumination which is felt at an intuitive, non-rational level and gained by direct experience, and (2) the authoritativeness or the certainty for the experiencer that such knowledge is truly or ultimately real, in contrast to the feeling that the experience was a subjective delusion. These two elements are connected because the knowledge through participation in ultimate reality (in the sense of being able to "know" and "see" what is really **real**), carries its own sense of certainty. Two kinds of reality must be distinguished in reading the accounts: (a) "ordinary" reality (the reality of usual, everyday consciousness), and (b) "ultimate" reality (awareness of another dimension not the same as "ordinary" reality but still quite "real" to the experiencer. In fact, "ultimate" reality may be judged to be more profoundly real that "ordinary" reality. In each individual case, the context must determine which type of reality is being mentioned or described.

Such insightful knowledge does not necessarily mean an increase in facts, but rather intuitive illumination. What becomes "known" (rather than intellectually assented to) is intuitively felt to be authoritative and requires no proof at a rational level, and has an inward feeling of objective truth. The content of this knowledge can be divided into two main types: insights into being and existence in general, and insights into one's personal, finite self. The certainty of the reality and significance of the content applies to both. Examples of insights about being and existence in general are the direct realization through the present experience of hitherto undreamed-of realities and possibilities of experience, new perspectives on old facts or ideas, new understanding of relationships and meanings, new appreciation of the universe as a whole, or an experience of "everything falling into place." Examples of insights about one's personal self are: a new certainty about vocational choice; realization of faults or problems to be met; understanding of the causes of conflict; or a clear vision of one's true self without self-deception. Such personal insights are at a level different from "ordinary" everyday reality.

Scoring level is based on the intensity of the certainty for the experiencer that the insightful knowledge gained is of "ultimate" reality (i.e., really **real** and not a delusion):
3 The characteristic of this level is the profundity of the conviction that "ultimate" reality has been encountered. The insightful knowledge is felt to be profoundly significant and true. The response of ultimate reality is total, and there is a feeling of being totally grasped and dealt with. There is no doubt that what is experienced and known is truly or ultimately real, and this conviction persists after the actual experience is over (even after 5 months).
2 The totalness and profundity of the certainty is lacking. There is some doubt as to the "ultimate" or true reality of the insights gained. Degree of certainty may decrease after the experience.
1 Insights are present, but at a less intense level of certainty of their "ultimate" reality than in 2. There is serious doubt as to their reality, but some conviction of reality remains, although it may be on the wane.

VII. **Paradoxicality**
Any use of paradoxical language in describing or interpreting the experience or its meaning should be scored in this category. Paradoxical language is defined as language which is logically contradictory in

statements about, descriptions of, or interpretations of the experience. Examples may include the experience of an empty, yet full and complete unity, the paradoxical loss of the sense of self and dissolution of individuality with retention of consciousness of what is experienced, or the separateness, yet unity with objects in the experience of external unity (paradoxical transcendence of space). Watch for descriptions of such paradoxical experiences.

Degree of paradoxicality is to be scored on how paradoxical any examples found appear to the judge, i.e., based on degree of intensity:
3 This level means that although obviously contrary to common sense, contradictory statements are still strongly stated as true descriptions of the experience. The examples are striking, and the account gives a strong impression of paradoxicality.
2 Contradictory statements appear only moderately paradoxical. The striking element is lacking.
1 Paradoxicality is present, but only to a low degree. The examples are not particularly impressive.

VIII. **Alleged Ineffability**
This category is for any mention or indication of difficulty in adequately describing one's own experience in words. Watch for comparisons with the person's previous ease or difficulty in describing his personal experiences. The tone of the whole account is important in judging this category.

Scoring level is based on the intensity of the indication of difficulty of description.
3 This level designates direct statements made with conviction that the experience is beyond words and verbal description.
2 This level reflects direct statements of ineffability which are made without the emphasis of level 3, or strong indirect indications from the account in general.
1 Statements give an impression of ineffability, but only weakly.

IX. **Persisting Changes in Attitude and/or Behavior after Six Months**
This category is for any **persisting** changes, positive or negative, in attitude and/or behavior which are a result of the experience. These changes are divided into sub-categories according to type of change, whether positive or negative. Phenomena occurring during the actual experience are not included, only their continuing effects in the life of the experiencer. Watch for changes occurring during the experience, or by the time of the initial write-up, and see if they are still present six months later.

The positive changes are divided into 4 main groups: A) toward self, B) toward others, c) toward life, d) toward the experience itself.

A) Increased integration of personality is the basic inward change in the personal **self**. Such integration in the form of a reorganization of the personality and growth in maturity may have developed relatively rapidly or slowly as a result of what occurred during the experience. (For example, from a radical experience of death and rebirth, or conversion, or as an effect of insight which was gained in the depth of the experience and gradually utilized later. Undesirable traits may be faced in a way that they can be dealt with and finally reduced or eliminated. Issuing from personal integration, the sense of one's inner authority may be strengthened, and the vigor and dynamic quality of life may be increased. Creativity and greater achievement-efficiency may be released. There may be an inner optimistic tone with consequent increase in feelings of happiness, joy, and peace.

B) Change in attitude and behavior toward **others** (includes more sensitivity, more tolerance, more real love, and more authenticity as a person by being more open and more one's true self with others. The response of others is a good indication of such changes, if mentioned.

C) Positive change in **life-attitude** or goal may include philosophy of life, sense of values, sense of meaning, purpose in life, vocational commitment, need for service to others, and new appreciation for life or the whole of creation. Life may seem richer. The sense of reverence may be increased, and more time may be spent in devotional life and meditation.

D) Positive attitude toward the **experience** means that it is regarded as valuable and that what has been learned is thought to be useful. The experience is remembered as a high point, and an attempt is made to recapture the experience or, if possible, to gain new experiences as a source of growth and strength. Mystical experiences of others are more appreciated and understood.

Negative changes are divided into the same four groups and include the negative counterparts of the positive elements mentioned above.

A) Personal disintegration is the basic change toward self and includes fear, anxiety, insecurity, loneliness, depression, despair, mental confusion, delusion, feeling of "unreality," regression in maturity, less dynamic quality and vigor, unhappiness, turmoil, inner pessimism.

B) Negative changes toward others include less effective interpersonal relations, withdrawal into self, friction, antagonism, hatred, less sensitivity, less tolerance, and less authenticity as a person.

C) Negative changes toward life may include a cynical and bitter attitude and less intensity in or loss of the positive items listed above under this sub-category.

D) Negative changes toward the experience include regret for participation and attempts to forget and suppress the experience. which may be regarded as harmful.

Scoring level is based on intensity of benefit or harmfulness. Decide to which sub-category each item of the six-month followup data belongs. Then score each sub-category according to the intensity communicated by the account.
3 This level means that the person feels strong or very strong benefit or harm.
2 This level indicated moderate benefit or harm.
1 This level indicates slight or questionable benefit or harm.

3. With the above categories in mind, read all the accounts through in succession, at one sitting.

4. Working on the accounts one at a time, in order:
a) Read the firs account straight through to get the general feel and tone. Feel free to mark in the margin in pencil, with the major category numbers (I to IX) any sentence which impresses you at the time as an obvious example of a particular category. Don't worry at this point about scoring intensity or completeness. Read to get an impression of the account as a whole.
b) Using the score sheet, read the account through and look for examples of category I (transcendence of time and/or space). Mark them with the category number. Then give a qualitative rating (0 to 3) fora each scoring division of this category, as indicated on the score sheet. Base your score on the highest level reached at any point in the experience. Thus an element mentioned only once may have been described in such a way as to indicate a 3-level experience. Rate on the basis of the highest level for **any** essential element of a particular scoring division, in accordance with the description of the category. Be sure to rate the experience of the person writing the account, not his description of what other people were experiencing.
c) Then read the same account through again and mark examples of categories II and III (positive mood and sense of sacredness). Score these items on the score sheet in the appropriate place. Follow this same procedure for the rest of the categories. Look for evidence of categories IV and V at one reading. Categories VII and VIII may also be combined in this way.
d) When you have finished the first account, do the same for each of the remaining ones, in order. Try to finish two accounts at least at one sitting.

Content Analysis Score Sheet Used by Judges with the Probability for each Item that the Difference between Experimentals and Controls was due to Chance[6]

Category	*p* values (for Experimentals)	
I. Transcendence of time or space		
A. Loss of usual sense of time	.001 (1)	
B. Loss of usual sense of space	.001(2)	
II. Positive mood		
A. Joy	.002 (3)	
B. Love	.035 (4)	
C. Peace or blessedness	(.063) (5)	
III. Sense of sacredness	(.37) (6)	
IV.Unity		
A. Internal unity	.002 (7)	
B. External unity		
1. Oneness through external objects other than people	(.25) (8)	
2. Oneness through people	.032 (9)	
V. Transciency of unity	.004 (10)	
VI. Objectivity and reality		
A. Insights into being and existence in general	.004 (11)	
B. Insights into personal finite self	(.11) (12)	
VII. Paradoxicality	.001 (13)	
VIII. Ineffability	.008 (14)	
IX. Persisting changes in attitude or behavior six months later	Positive	Negative
A. Toward self	.004 (15)	(.13) (16)
B. Toward others	(.50) (17)	(1) (18)
C. Toward life	.016 (19)	(1) (20)
D. Toward the experience	(.19) (21)	(.25) (22)

Reliability of Judges as Determined from Kendall Rank Correlation Coefficient[7]

Judge Compared	τ	*p* less than
A and B	.74	.00006
B and C	.88	.00006
C and A	.78	.00006
All three	.80	.00006

---

6. The Sign Test was used to calculate *p* values from judges' scores.
7. Siegel, *op. cit.*, pp. 213-223.

Appendix F

EXPLANATION OF THE COLUMNS AND SYMBOLS USED IN THE CATEGORY TABLES

TABLE 3
Category I: UNITY
Combination of All Subcategories

	Subject group	Frequency Distribution (Number of *times* scored)				Total score (10 subjects)		Sign Test Statistics	
Items[a]	**(*n*=10)**[b]	**Strong**	**Moder.**	**Slight**	**None**[c]	**Actual**	**Maximum**[d]	***N***	***p***[e]

[a] The items which were combined from either the post-drug, follow-up, or content-analysis data.

[b] The group of subjects, either 10 experimentals or 10 controls.

[c] Frequency distribution shows the total **number** of responses made by all experimentals and controls at the particular scoring level indicated. The scoring scales on the three methods of measurement were correlated for easy comparison (i.e., the "strong" level for each rating scale was not the same numerical value. This level represented a score of "three" on the content-analysis scale, "four" on the post-drug questionnaire scale, and both "four" and "five" on the follow-up questionnaire scale. The "slight" level represented a score of "one" on content-analysis scale, and both "one" and "two" on the questionnaire scales).

[d] The sum of the **weighted** scores at each level. Maximum is the sum which would have been obtained if all the subjects scored all the items at the highest possible level.

[e] *N* = number of matched pairs with a difference in score when the score of the control subject was subtracted from the score of the experimental subject. The prediction had been made that the experimental score would be higher. The maximum value of *N* = 10.

p = the probability that the predicted higher scores of the experimentals were due to chance.

Appendix G

DATA NOT DIRECTLY RELEVANT TO CATEGORIES OF THE TYPOLOGY OF MYSTICISM

Group I: Integrative and Constructive Phenomena

Phenomena which occurred during experience	**values *p* (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug data:		
P3 Sense of the preciousness of life:	.020	.032
P88a Death experience:	.032	(.13)
P89a Rebirth experience:	.032	(.13)
P86a New significance to life:	(.062)	(.063)
P95a Conversion experience:	(.35)	(.35)
P21 Sense of forgiveness or cleansing:	(.35)	(.35)
P84a Increased integration of personality:	(.37)	(.37)
P10 Easy understanding of feelings of others:	(.5)	(.5)

P2 Feeling of unity with your group:	(.64)	(.64)
P93a Felt need for some type of service to others:	(.5)	(.5)
(2) Follow-up data:		
F21 Rebirth experience:	.016	(.063)
F20 Meaningfulness of your own life:	.055	(.062)
Phenomena which occurred within a few days after the experience (all from post-drug data):		
P86b New significance to life:	.002	.032
P96b Sense of belonging to a new and greater unity:	(.063)	(.063)
P126 Your experience was valuable to you personally:	(.062)	(.062)
P127 Your experience was mystical or religious:	(.062)	(.062)
P88b Death experience:	(.063)	(.25)
P84b Increased integration of personality:	(.090)	(.063)
P92b Felt need for some type of service to others:	(.18)	(.18)
P89b Rebirth experience:	(.19)	(.19)
P93b Actual changes in behavior in ways you would consider constructive and positive:	(.18)	(.18)
P95b Conversion experience:	(.19)	(.19)

Group II: Disturbing Changes in Attitude and Behavior

Phenomena which occurred during experience	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Fear and Anxiety:		
P5 Terror or fear:	.004	.008
P15 Fear of losing control:	.004	(.13)
P121 Anxious about having to "come out of it":	.008	.008
P8 Panic:	.016	(.25)
P46 Insecurity:	(.11)	(.063)
P51 Anxiety:	(.26)	(.26)
(2) Melancholia:		
P22 Sense of loneliness or aloneness:	.02	.032
P48 Despair:	.02	.032
P40 Depression:	(.09)	(.25)
P87a Lessening of significance to life:	(.13)	(.25)
(3) Disorientation:		
P98a Confusion of thinking:	.004	(.063)
P99a Feelings of unreality:	.016	(.13)
P101a Loss of memory:	.035	(.13)
P85a Disintegration or destructive effects on personality:	(.062)	(.25)
P97a Sense of subjective delusion:	(.063)	(1)
P17 Feeling that you were going to die during the experience:	(.063)	(1)

P19 General sense of sin:	(.50)	(.50)
P20 Conviction of certain specific sins in your life:	(.50)	(1)
P25 Sense of judgment on your life:	(.78)	(.78)
(4) Antisocial Feelings or Behavior:		
P123 Dislike for either leader:	.032	(1)
P91a Feelings of antagonism and hate toward others:	(.090)	(1)
P45 Meanness:	(.19)	(1)
P120 Explosive anger or fury:	(.13)	(1)
P94a Sense of increased self-centredness:	(.11)	(1)
P125 Dislike for any participant in the experiment:	(.37)	(1)
P42 Hate:	(.35)	(1)
Phenomena which occurred within a few days after the experience (all from post-drug data):		
P101b Loss of memory for part of the experience:	.020	(1)
P98b Confusion of thinking:	.032	(1)
P99b Feelings of unreality:	(.063)	(.13)
P97b Sense of subjective delusion:	(.063)	(1)
P85b Disintegration or destructive effects on personality:	(.13)	(1)
P87b Lessening of significance to life:	(1)	(1)
P91b Feelings of antagonism and hate toward others:	(.25)	(1)
P94b Sense of increased self-centeredness:	(.25)	(1)
Phenomena which occurred within six months after the experience:		
F74a Increased feelings of anxiety:	.032	(1)
F61a Increased feelings of depression:	(.063)	(1)
(See part III of Follow-up Questionnaire in Appendix D for the remaining negative items, none of which proved significant - *p* greater than .1)		

Group III: Physical Sensations

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
P16 Seeing a light which appeared to have no naturally explainable source:	.016	(.13)
P102 Loss of consciousness:	.016	(.25)
P103 Distortion of visual perception:	.055	(.063)
P104 Colors more intense:	.001	.008
P105 Visions of colors, geometric patterns, objects, animals, people, scenes:	.001	.008
P106 Seeing colors around heads or bodies of others:	.032	(1)
P108 Unusual odors or scents:	(.063)	(1)
P114 Sensation of floating:	(.09)	(.13)
P119 Sense of being out of the body:	(.062)	(.13)
P112 Nausea:	.008	(1)
P115 Sense of bodily warmth:	.035 (for controls)	(1)

P116 Itching or burning of skin:	.011 (for controls)	(.25)
(See items P100-P118 on post-drug questionnaire in Appendix C - for items above .1 level.)		

Group IV: Miscellaneous

	***p* values (for experimentals)**	
	Using all scores:	Using only "strong" scores:
(1) Post-drug data:		
P128 Got psilocybin:	.001	.007
(2) Follow-up data:		
F80b You place less importance on traditional theological formulations to express spiritual insights:	.035	(.25)
F100a You are convinced you had psilocybin:	.001	.001
F100b ...did not have psilocybin:	.001 (for controls)	.001

On Good Friday, 1962, before services commenced in Boston University's Marsh Chapel, Walter Pahnke administered small capsules to twenty Protestant divinity students. Thus began the most scientific experiment in the literature designed to investigate the potential of psychedelic drugs to facilitate mystical experience (Pahnke, 1963, 1966, 1967, 1970; Pahnke & Richards, 1969a, 1969b, 1969c). Half the capsules contained psilocybin (30mg), an extract of psychoactive mushrooms, and the other half contained a placebo. According to Pahnke, the experiment determined that "the persons who received psilocybin experienced to a greater extent than did the controls the phenomena described by our typology of mysticism" (Pahnke, 1963, p. 220).

This paper is a brief methodological critique and long-term follow- up study to the "Good Friday Experiment." Pahnke, who was both a physician and a minister, conducted the experiment in 1962 for his Ph.D. in Religion and Society at Harvard University, with Timothy Leary as his principal academic advisor (Leary, 1962, 1967, 1968). Describing the experiment, Walter Houston Clark, 1961 recipient of the American Psychological Association's William James Memorial Award for contributions to the psychology of religion, writes, "There are no experiments known to me in the history of the scientific study of religion better designed or clearer in their conclusions than this one" (Clark, 1969, p. 77).

Since a classic means of evaluating mystical experiences is by their fruits, follow-up data is of fundamental importance in evaluating the original experiment. A six-month follow-up was part of the original experiment and a longer term follow-up would probably have been conducted by Pahnke himself had it not been for his death in 1971. For over twenty-five years it has not been legally possible to replicate or revise this experiment. Hence, this long-term follow-up study, conducted by the author, is offered as a way to advance scientific knowledge in the area of psychedelics and experimental mysticism. Lukoff, Zanger and Lu's review (1990) of psychoactive substances and transpersonal states offers a recent overview of this topic.

Though all raw data from the original experiment is lost, including the uncoded list of participants, extensive research over a period of four years and the enthusiastic cooperation of most of the original subjects have resulted in the identification and location of nineteen out of the original twenty subjects. From November, 1986 to October, 1989, this author tape recorded personal interviews with sixteen of the original subjects, meeting fifteen in their home cities throughout the United States and interviewing one subject (from the control group) over the telephone. In addition to the interviews, all sixteen subjects participating in the long-term follow-up, nine from the control and seven from the experimental group, were re-administered the six-month 100- item follow-up questionnaire used in the original experiment.

Of the remaining three subjects from the experimental group, one is deceased. The identity of another is unknown. One declined to participate citing concerns about privacy. One subject, from the control group, declined to be interviewed or to fill out the questionnaire because he interpreted Pahnke's pledge of confidentiality to mean that the subjects should not talk about the experiment to anyone. This author's discussion of the meaning of confidentiality and mention of the explicit support for the long-term follow-up by Pahnke's wife failed to enlist his participation.

Informal discussions were also conducted with seven out of the ten of Pahnke's original research assistants for purposes of gathering background information about the experiment. At the time of the experiment, these people were professors or students of religion, psychology and philosophy at universities, colleges and seminaries in the Boston area.

Methodology of the original experiment

Pahnke hypothesized that psychedelic drugs, in this case psilocybin, could facilitate a "mystical" experience in religiously inclined volunteers who took the drug in a religious setting. He further hypothesized that such experiences would result in persisting positive changes in attitudes and behavior.

Pahnke believed the most conducive environment for his experiment would be a community of believers participating in a familiar religious ceremony designed to elicit religious feelings, in effect creating an atmosphere similar to that of the tribes which used psilocybin-containing mushrooms for religious purposes (Harner, 1973; Hofmann, Ruck & Wasson, 1978; Hofmann & Schultes, 1979; Wasson, 1968). Accordingly, the experiment was designed to administer psilocybin to a previously acquainted group of Christian divinity students in church during a Good Friday service.

Methodologically, the study was designed as a randomized controlled, matched group, double-blind experiment using an active placebo. Prior to Good Friday, twenty white male Protestant volunteers, all of whom were students at the same theological school in the Boston area, were given a series of psychological and physical tests. Ten sets of closely matched pairs were created using variables such as past religious experience, religious background and training, and general psychological makeup. On the morning of the experiment, a helper who did not participate further in the experiment and who did not know any of the subjects, flipped a coin to determine to which group, psilocybin or placebo, each member of the pair would be assigned.

Three different methods were used to create numerical scales quantifying the experiences of the subjects in terms of an eight-category typology of mystical experiences designed by Pahnke especially for the experiment. Blind independent raters trained in content-analysis procedures scored descriptions of the experiences written by the subjects shortly after Good Friday as well as transcripts of three separate tape-recorded interviews conducted immediately, several days and six months after the experiment. A 147-item questionnaire was administered to the subjects one or two days after Good Friday and a 100-item questionnaire was administered six months after the experiment. The subject's responses to the interview and the two questionnaires were transformed into three distinct scores averaging the percentage of the maximum possible score in each category. Each of the three complementary scores was then compared to each other.

Pahnke secured support and permission to use Marsh Chapel from Rev. Howard Thurman, Boston University's dynamic black chaplain. Several small meeting rooms and a self-contained basement chapel were set aside on Good Friday for the participants in the experiment while the main service led by Rev. Thurman was taking place upstairs in the larger chapel. The two-and-a-half hour service was broadcast into the basement chapel, where altar, pews, stained glass windows and various religious symbols were permanently located.

Pahnke gave an active placebo of nicotinic acid to the controls who were expecting to receive either the psilocybin or an inactive placebo. This was done in order to "potentiate suggestion in the control subjects, all of whom knew that psilocybin produced various somatic effects, but none of whom had ever had psilocybin or any related substance before the experiment" (Pahnke, 1963, p. 89).

The ten research assistants worked as part of the experimental team in order to provide emotional support to the subjects prior to and during the service. Subjects were divided into five groups of four with two research assistants, known as group leaders, assigned to each group. These small groups met for two hours prior to the service to build trust and facilitate group support. Subjects were encouraged to "go into the unexplored realms of experience during the actual experiment and not try to fight the effects of the drug even if the experience became very unusual or frightening" (Pahnke, 1963, p. 96).

As a precaution against biasing the subjects toward the typology of mystical experience, leaders were told not to discuss specific aspects of the psychedelic or mystical experience. The lack of overt bias was confirmed by all of the subjects in their long-term follow-up interviews. In a typical long-term follow-up report, psilocybin subject S.J. (all initials used to identify subjects are coded to preserve anonymity) made the following remarks both about the preparation phase of the experiment and the conduct of the group leaders:

> None of the fine points of the mystical experience were given to us. We were not told to read any books such as Stace's book on mysticism or Jacob Boheme's books, nothing like that. They did not bias us in any way towards that, not at all.

At the insistence of one of the group leaders as well as Pahnke's faculty sponsor, Timothy Leary, but over the objections of Pahnke, all of the group leaders were also given a pill prior to the service (Leary, 1984, p. 107). This was done in a double-blind manner with one of each group's leaders receiving a half dose of psilocybin (15 mg) and the other the placebo. Pahnke was concerned this would lead to charges of experimenter bias being leveled against the study, but Leary and the group leader felt that the full involvement of the group leaders would create more of a community feeling and lend necessary confidence to the subjects. Though administered a capsule at the Good Friday service, the group leaders' reactions were not tape recorded, nor did they fill out questionnaires. Pahnke himself refrained from having any personal experiences with any psychedelic drug until after die experiment and follow-up had been completed.

Difficulties with the Double-Blind

The double-blind was successfully sustained through all of the preparation phases of the experiment up to and including ingestion of the capsule. The double-blind was even sustained for a portion of the Good Friday service itself because of the use of nicotinic acid as an active placebo. Nicotinic acid acts more quickly than does psilocybin and produces a warm flush through vasodilation of blood vessels in the skin and general relaxation. Subjects in the placebo group mistakenly concluded, in the early stages of the experiment, that they were the ones who had received the psilocybin (Pahnke, 1963, p. 212). The group leaders, unaware that an active placebo was going to be used, were also initially unable to distinguish whether subjects had received the psilocybin or the placebo.

Psilocybin's powerful subjective effects were eventually obvious to all subjects who received it, even though they had not previously ingested the drug or anything similar to it (Pahnke, 1963, p. 212). Inevitably, the double-blind was broken during the service as the psychoactive effects of the psilocybin deepened and the physiological effects of the nicotinic acid faded. At the end of the day of the experiment, all subjects correctly determined whether they had received the psilocybin or the placebo even though they were never told which group they were in (Pahnke, 1963, p. 210). Pahnke himself remained technically blind until after the six month follow-up. The comments of subject O.W., gathered in the course of this author's long-term follow-up, are typical of members of the control group.

> After about a half hour I got this burning sensation. It was more like indigestion than a burning sensation. And I said to T.B., "Do you feel anything?" And he said, "No, not yet." We kept asking, "Do you feel anything?" I said, "You know, I've got this burning sensation, and it's kind of uncomfortable." And T.B. said, "My God, I don't have it, you got the psilocybin, I don't have it." I thought, "Jeez, at least I was lucky in this trial. I'm sorry T.B. didn't get it, but I'm gonna' find out." I figured, with my luck, I'd probably get the sugar pill, or whatever it is. And I said to Y.M., "Do you feel anything?" No, he didn't feel anything. So I sat there, and I remember sitting there, and I thought, "Well, Leary told me to chart my course so I'm gonna concentrate on that." And I kept concentrating and sitting there and all I did was get more indigestion and uncomfortable.
>
> Nothing much more happened and within another 40 minutes, 45 minutes, everybody was really

> quiet and sitting there. Y.M. was sitting there and looking ahead, and all of the sudden T.B. says to me, "Those lights are unbelievable." And I said, "What lights?" He says, "Look at the candles." He says, "Can you believe that?" And I looked at the candles, and I thought, 'They look like candles." He says, "Can't you see something strange about them?" So I remember squinting and looking. I couldn't see anything strange. And he says, "You know it's just spectacular." And I looked at Y.M. and he was sitting there saying, "Yeah." And I thought, "They got it, I didn't."

The follow-up interviews yielded no evidence that the experimental team consciously used their knowledge of which pill the subjects had received to bias the results. However, unconscious bias resulting in an "expectancy effect" cannot be ruled out (Barber, 1976). Still, valuable information can be generated without the successful use of the double-blind methodology. Louis Lasagna, Director of the Center for the Study of Drug Development at Tufts University, writes:

> We have witnessed the ascendancy of the randomized, double-blind, controlled clinical trial (RCCT), to the point where many in positions of authority now believe that data obtained via this technique should constitute the only basis for registering a drug or indeed for coming to any conclusions about its efficacy at any time in the drug's career. My thesis is that this viewpoint is untenable, needlessly rigid, unrealistic, and at times unethical. ... Modern trial techniques [were not] necessary to recognize the therapeutic potential of chloral hydrate, the barbiturates, ether, nitrous oxide, chloroform, curare, aspirin, quinine, insulin, thyroid, epinephrine, local anesthetics, belladona, antacids, sulfonamides, and penicillin, to give a partial list. ... (Lasagna, 1985, p. 48).

Commenting about the attempt to remove the experimenter from the experiment completely, Tooley and Pratt remark:

> In certain participant-observer situations (e.g. psychotherapy, education, change induction, action research) the purpose might be to influence the system under investigation as much as possible, but still accounting for (though now exploiting) the variance within the system attributable to the several significant and relevant aspects of the investigator's participant observation. ... From this perspective, the quixotic attempt to eliminate the effects of participant-observation in the name of a misplaced pseudo-objectivity is fruitless, not so much because it is impossible but because it is unproductive. ... From our point of view... the question becomes not how to eliminate bias (unaccounted-for influence) of participant observation, but how optimally to account for and exploit the effects of the participant observation transaction in terms of the purposes of the research (Tooley & Pratt, 1964, p. 254-56).

The loss of the double-blind makes it impossible to determine the relative contributions of psilocybin and suggestion in producing the subjects' reported experiences. If the experiment were designed specifically to measure the pure drug effects of psilocybin, the failure of the double-blind would be quite damaging. In this instance the loss of the double-blind is of lesser significance because the entire experiment was explicitly designed to maximize the combined effect of psilocybin and suggestion. The setting was religious, the participants were religiously inclined and the mood was positive and expectant. Pahnke did not set out to investigate whether psilocybin was able to produce mystical experiences irrespective of preparation and context. He designed the experiment to determine whether volunteers who received psilocybin within a highly supportive, suggestive environment similar to that found in the ritual use of psychoactive substances by various native cultures would report more elements of a classical mystical experience (as defined by the questionnaires) than volunteers who did not receive psilocybin. The loss of the double-blind may have enhanced the power of suggestion to some extent and suggests that restraint should be used in attributing the experiences of the experimental group exclusively to the psilocybin (Zinberg, 1984).

Critique of the Questionnaire

Pahnke designed the questionnaire he used to measure the occurrence of a mystical experience specifically for the experiment. No similar questionnaires existed at the time (Larson, 1986; Rue, 1985; Silverman, 1983). Pahnke decided to measure the mystical experience in reference to eight distinct experiential categories. The categories include 1) sense of unity, 2) transcendence of time and space, 3) sense of sacredness, 4) sense of objective reality, 5) deeply felt positive mood, 6) ineffability, 7) paradoxicality and 8) transiency. These categories are very similar to those elaborated by such well-respected scholars of mystical experience as William James (1902), Evelyn Underhill (1910), and W.T. Stace (1960) and are accepted as valid even by academic critics of the Good Friday experiment such as R.C. Zaehner (1972). At present, the scientific questionnaire most widely used by researchers to assess mystical experiences is a 32-item questionnaire created by Ralph Hood, also based on categories developed by W.T. Stace (Spilka, Hood & Gorsuch, 1985).

Zaehner's critique of Pahnke's questionnaire is that it does not contain a category for experiences which are specifically Christian, such as identification with the death and rebirth of Jesus Christ. From Zaehner's perspective, this omission made it impossible to determine if the experiences reported by the subjects during the Good Friday experiment were religious, since he thought a religious experience for Christians necessarily involves a theistic encounter with Christ. Zaehner objected to the claim that an experience of a generalized, non-specific, apprehension of a transcendent reality beyond any specific cultural forms and figures could properly be called religious. Anticipating this critique, Pahnke asserted in the thesis that he was not attempting to resolve the question of what can properly be called religious but was simply investigating mystical experiences, regardless of whether or not they were considered religious. This author will also leave this delicate discussion to others.

The questionnaire used in the Good Friday experiment has been modified and expanded oyer the years by Pahnke, William Richards, Stanislav Grof, Franco Di Leo, and Richard Yensen for use in subsequent psychedelic research (Richards, 1975, 1978). From the initial creation of the questionnaire by Pahnke in 1962 to Di Leo and Yensen's computerized version, called the Peak Experience Profile, the basic items relating to the mystical experience have remained essentially unchanged (Di Leo, 1982). While the original follow-up questionnaire was composed of eight different categories, the Peak Experience Profile uses only six. The category of transiency was eliminated since it measures any altered state of consciousness whether mystical or not. The paradoxicality and alleged ineffability categories were combined into the ineffability category. Over the years, new categories measuring transpersonal but not necessarily mystical experiences were added. For example, new questions relate to the reexperiencing of the stages of birth and the perinatal matrixes as defined by Grof (Grof, 1975, 1980) and also to past-life experiences (Ring, 1982, 1984, 1988). A series of questions relating to difficult and painful nadir experiences, in some sense the opposites of peak experiences, has also been added.

In Pahnke's original questionnaire and in the subsequent revisions, the completeness with which each subject experienced each category is measured through numerical responses to category- specific questions. Pahnke's subjects rated each question on the post-drug questionnaire from zero to four, with zero indicating that the item was not experienced at all and four indicating that it was experienced as strong or stronger than ever before. The six-month follow-up questionnaire used a zero to five scale, with four indicating that it was experienced as strong as before and five indicating that it was experienced stronger than ever before.

The questions themselves are of two types. The predominant type asks the subject about experiences of a new perspective. For example, some of the questions used to determine the sense of unity ask subjects to rate the degree to which they experienced a pure awareness beyond any empirical content, a fusion of the self into a larger undifferentiated whole, or a freedom from the limitations of the self in connection with a unity or bond with what was felt to be all-encompassing and greater-than-self. These type of questions are sufficiently detailed and specific to be an effective test for the specific category.

The second type of question, used much less frequently, asks about the loss of a normal state. For example, two questions used to determine the presence of a sense of unity simply required subjects to rate the degree to which they lost their sense of self or experienced a loss of their own identity. This type of question is a minor weak point of the questionnaire because it can be rated highly without having anything to do with mystical experiences. For example, one subject reported in the follow-up interview that under the influence of psilocybin he temporarily had difficulty recalling his career choice, home, names of his wife and children, and even his own name. This experience of a powerful loss of the usual sense of self and identity would be highly correlated with mystical experience in the questionnaire but may not actually be related because it can occur for a variety of reasons. Though the questionnaire has relatively few of this type of question, some overestimation of the completeness of the mystical experience could have been introduced into the data as a result.

In addition to asking questions about the experience itself, the follow-up questionnaire also sought to assess the effects of that experience on the attitudes and behaviors of the subjects. For example, the subjects' attitude changes were assessed by asking them to use a 0 to 5 scale to rate whether they had experienced an increase or a decrease in their feelings of happiness, joy, peace, reverence, creativity, vocational commitment, need for service, anxiety, and hatred. Changes in subjects' behavior were assessed by means of questions asking whether or not they experienced changes in their relationships with others, in time spent in quiet meditation or devotional life, or whether they thought their behavior had changed in positive or negative ways.

Pahnke's questionnaire gathered information only from the selfreports of the subjects, resulting in a general sense of the subjects' own assessment of the direction of the effects of their Good Friday experience. The data do not yield specific information about the internal psychodynamic mechanisms at work within each subject, nor do they include the views of significant others regarding the effects of the experiment on the subjects. In contemporary psychotherapy research, more sophisticated methods than Pahnke's are used to assess personality change (Beutler & Crago, 1983). Reports from significant others such as family members and close friends of the subject are almost always used to add an important "objective" element in assessing personality change. Data from the follow-up questionnaires, administered by Pahnke at six-months and by the author after twenty-four to twenty-seven years, should be considered valuable as far as they go, but this is not very far. Since no detailed personality tests were given prior to the experiment, results of such tests at the time of the long-term follow-up would have been of little value and were not conducted. The long-term follow-up interviews, because of their open-ended format and extensive questioning, yielded more detailed information than the questionnaire about the content of the experiences and the persisting effects.

Findings of the original study and long-term follow-up

Pahnke arbitrarily determined that for a mystical experience to be considered complete for the purposes of the experiment, out of the maximum total possible score, "the total score and the score in each separate category must be at least 60 to 70 percent" (Pahnke, 1967, p. 66). According to this cut-off point, "Four of the ten psilocybin subjects reached the 60 to 70 percent level of completeness, whereas none of the controls did" (Pahnke, 1967, p. 64). Looked at by subjects and categories, Pahnke reported that "eight out of ten of the experimental subjects experienced at least seven out of the nine categories. None of the control group, when each individual was compared to his matched partner, had a score which was higher" (Pahnke, 1966, p. 647). In every general category and in every specific question, the average score of the experimental subjects exceeded that of the control subjects. The differences between the groups in the scores on the questionnaires were significant at $p<.05$ level for all categories.

When asked at a conference if any of the controls had a mystical experience, Pahnke replied:

> To take an individual case, there was one control subject who scored fairly high on sacredness and sense of peace and that he himself, in his written account, said "It was a very meaningful experience, but in the past I've certainly had one that was much more so" (Pahnke, 1966, p. 648).

Pahnke's six-month follow-up data and the author's long-term follow-up questionnaire data, both of which used the same instrument, are displayed in Table 1. The six-month scores are listed first and the long-term follow-up scores follow in parentheses. For each category, the percentages in the chart represent the total scores of the subjects divided by the highest possible scores that could have been reported. The numbers measure the completeness with which each category was experienced.

Comparisons can reliably be made between the control group's six-month and long-term scores because nine out of the original ten control group subjects participated in the long-term follow-up and the variance in scores between control subjects was small. The absence of completed long-term questionnaires from three of the ten original subjects from the psilocybin group makes comparing their six-month and long-term scores more difficult. The long-term follow-up interviews produced specific information suggesting that one of the three missing psilocybin subjects had scores significantly lower than average. No information was generated suggesting that the other two missing subjects had scores significantly different than average. The average scores for the long-term follow-up may thus overstate somewhat the scores from the entire psilocybin group.

The average scores for the eight categories of the mystical experience and the scores for persisting positive and negative changes in attitude and behavior have changed remarkably little for either the controls or the experimentals despite the passage of between twenty-four and twenty-seven years between the two tests. The questionnaire seems to be reliable and indicates that time has not substantially altered the opinions of the subjects about their experiences. In the long-term follow-up even more than in the six-month follow-up, the experimental group has higher scores than the control group in every category. For the long-term follow-up, these differences are significant at p<.05 in every category.

TABLE 1.
"GOOD FRIDAY EXPERIMENT" EXPERIMENTAL AND CONTROL GROUPS
AT SIX-MONTH AND LONG-TERM FOLLOW-UP,
SHOWN AS PERCENTAGES OF MAXIMUM POSSIBLE SCORES

CATEGORY	EXPERIMENTALS		CONTROLS	
	Six-month	Long-Term	Six-month	Long-Term
1. Unity A. Internal B. External	60 39	(77) (51)	5 1	(5) (6)
2. Transcendence of Time and Space	78	(73)	7	(9)
3. Deeply Felt Positive Mood	54	(56)	23	(21)
4. Sacredness	58	(68)	25	(29)
5. Objectivity and Reality	71	(82)	18	(24)
6. Paradoxicality	34	(48)	3	(4)
7. Alleged Ineffability	77	(71)	15	(3)
8. Transiency Average for the Categories	76 60.8	(75) (66.8)	9 11.8	(9) (12.2)
9. Persisting Positive Changes in Attitude and Behavior	48	(50)	15	(15)
10. Persisting Negative Changes in Attitude and Behavior	6	(6)	2	(4)

At Six-Month Follow-up, Exper. N=10, Control = 10
Long-Term Follow-Up (In Parenthesis) Exper. N=7, Control N=9
p<.05 for all category comparisons at both six-months and long-term

For the experimental group, the average score for the mystical categories at the six-month follow-up was 60.8 percent. They scored 66.8 percent at the long-term follow-up. In the six-month follow-up, the experimental group scored above 34 percent in all categories while in the long-term follow-up they scored above 48 percent in all categories. The experimental group scored the highest in those categories that typify a different state of consciousness such as transcendence of time and space, alleged ineffability and transiency.

For the control group, the average score for the eight categories of mystical experience at the six-month follow-up was 11.8 percent. They scored 12.2 percent at the long-term follow-up. The highest score of the control group at either time was 29 percent, in the sacredness category. The control group scored the highest in the categories of experience that religious services are most likely to induce, namely sense of sacredness, deeply felt positive mood and sense of objectivity and reality.

For the psilocybin group, the long-term follow-up yielded moderately increased scores in the categories of internal and external unity, sacredness, objectivity and reality, and paradoxicality, while all other categories remained virtually the same as the six-month data. Several decades seem to have strengthened the experimental groups' characterization of their original Good Friday experience as having had genuinely mystical elements. For the controls, the only score that changed substantially was that of alleged ineffability, which decreased.

A relatively high degree of persisting positive changes were reported by the experimental group while virtually no persisting positive changes were reported by the control group. In the open-ended portion of the long-term follow-up questionnaire, experimental subjects wrote that the experience helped them to resolve career decisions, recognize the arbitrariness of ego boundaries, increase their depth of faith, increase their appreciation of eternal life, deepen their sense of the meaning of Christ, and heighten their sense of joy and beauty. No positive persisting changes were reported by the control group in the open-ended section of the follow-up questionnaire.

There was a very low incidence of persisting negative changes in attitudes or behavior in either group at either the six-month follow-up or the long-term follow-up. However, the one psilocybin subject reported to have had the most difficult time during the experiment was the one who declined this author's request to be interviewed in person or fill out a questionnaire, placing in question the generalizability of this finding for the long-term.

Both the six-month and long-term follow-up questionnaire results support Pahnke's hypothesis that psilocybin, when taken in a religious setting by people who are religiously inclined, can facilitate experiences of varying degrees of depth that either are identical with, or indistinguishable from, those reported in the cross-cultural mystical literature. In addition, both the six-month and the long-term follow-up questionnaire results support Pahnke's hypothesis mat the subjects who received psilocybin, more so than the controls, experienced substantial positive persisting effects in attitude and behavior.

The long-term follow-up interviews: General overview

This long-term follow-up was conducted roughly a quarter century after the subjects participated in the original experiment. All subjects contacted live in the United States, with five out of the eight psilocybin subjects and five out of the ten placebo subjects currently working as ministers. Other professions represented are stockbroker, lawyer, community developer, social worker, administrative- assistant and educator. Except for one of the psilocybin subjects, all are currently married. All are working and self-supporting. All but two welcomed the opportunity to discuss their participation in the Good Friday experiment.

Each of the psilocybin subjects had vivid memories of portions of their Good Friday experience. For most this was their life's only psychedelic experience, in part because there have been no legal opportunities for such experiences for the last twenty-five years in the United States (or in any of the roughly 90 countries who are party to the international drug control treaties coordinated by the United Nation's World Health Organization). The experimental subjects unanimously described their Good Friday psilocybin experience as having had elements of a genuinely mystical nature and characterized it as one of the highpoints of their spiritual life. Some subjects reported that the content of their experience was specifically involved with the life of Christ and related directly to the Christian message while others had experiences of a more universal, non-specific nature. Most of the control subjects could barely remember even a few details of the service.

Most of the psilocybin subjects had subsequent experiences of a mystical nature with which they were able to compare and to contrast to their psilocybin experience. These subsequent experiences occurred either in dreams, in prayer life, in nature or with other psychedelics and seemed to the psilocybin subjects to be of the same essential nature as their Good Friday experience. Significant differences between their non-drug and drug mystical experiences were noted, with the drug experiences reportedly both more intense and composed of a wider emotional range than the non-drug experiences. The non-drug experiences were composed primarily of peaceful, beautiful moments experienced with ease while the drug experiences tended to include moments of great fear, agony and self-doubt.

The discussion of Subject T.B. about the relationship between his psilocybin and his other mystical experiences illustrates how the subjects saw the validity of their psilocybin experiences.

> I can think of no experiences [like the Good Friday experience] quite of that magnitude. That was the last of the great four in my life. The dream state ... I had no control over when it was coming. It was when I [was about nine and] had scarlet fever and rheumatic fever, apparently at either similar or at the same times. And they thought that I was going to die. And I saw a light coming out of the sky, this is in the dream, and it came toward me and it was like the figure of Christ and I said, "No, let me live and I'll serve you." And I'm alive and I've served. The prayer state when I was in seventh grade was very similar in the way it happened to me. I intentionally went for an experience with God. In seventh grade. And I also went for an experience with God at the Good Friday experience. And those were similar. The West Point experience was different. In that yes,

> it was prayers, it was on my knees, it was there, but the face of Christ was ... it happened more to me than me participating in it. It was more like a saving experience kind of thing. So I've had that and can talk about "a salvation experience," a born again experience, it was that kind of dedication.

Each of the psilocybin subjects felt that the experience had significantly affected his life in a positive way and expressed appreciation for having participated in the experiment. Most of the effects discussed in the long-term follow-up interviews centered around enhanced appreciation of life and of nature, deepened sense of joy, deepened commitment to the Christian ministry or to whatever other vocations the subjects chose, enhanced appreciation of unusual experiences and emotions, increased tolerance of other religious systems, deepened equanimity in the face of difficult life crises, and greater solidarity and identification with foreign peoples, minorities, women and nature. Subject K.B.'s description of the long-term effects is representative. He remarks:

> It left me with a completely unquestioned certainty that there is an environment bigger than the one I'm conscious of. I have my own interpretation of what that is, but it went from a theoretical proposition to an experiential one. In one sense it didn't change anything, I didn't discover something I hadn't dreamed of, but what I had thought on the basis of reading and teaching was there. I knew it. Somehow it was much more real to me. ... I expect things from meditation and prayer and so forth that I might have been a bit more skeptical about before. ... I have gotten help with problems, and at times I think direction and guidance in problem solving. Somehow my life has been different knowing that there is something out there. ... What I saw wasn't anything entirely surprising and yet there was a powerful impact from having seen it.

In addition to self-reports, several subjects who had stayed in contact with each other over the years spoke about the effects they noticed in each other. In the instances where such information was obtained, the observations of fellow subjects were similar to the self-reports and confirmed claims of beneficial effects.

Several of the psilocybin subjects discussed their deepened involvement in the politics of the day as one result of their Good Friday experience. Feelings of unity led many of the subjects to identify with and feel compassion for minorities, women and the environment. The feelings of timelessness and eternity reduced their fear of death and empowered the subjects to take more risks in their lives and to participate more fully in political struggles.

Subject T.B. discussed how his perception of death during the Good Friday experience affected his work in the political field. He remarked:

> When you get a clear vision of what [death] is and have sort of been there, and have left the self, left the body, you know, self leaving the body, or soul leaving the body, or whatever you want to call it, you would also know that marching in the Civil Rights Movement or against the Vietnam War in Washington [is less fearful]. ... In a sense [it takes away the fear of dying] ... because you've already been there. You know what it's about. When people approaching death have an out-of-body experience ... [you] say, "I know what you're talking about. I've been there. Been there and come back. And it's not terrifying, it doesn't hurt. ..."

Subject S.J. found that his Good Friday experience of unity supported his efforts in the political field.

> I got very involved with civil rights after that [his psychedelic experience] and spent some time in the South. I remember this unity business, I thought there was some link there. ... There could have been. People certainly don't write about it. They write about it the opposite way, that drugs are an escape from social obligations. That is the popular view. ...

Only one of the control subjects felt that his experience of the Good Friday service resulted in beneficial personal growth. That particular control subject thought he was probably the one in the original experiment reported to have had a partial mystical experience. Ironically, he felt that the most important benefit he received from the service was the decision to try psychedelics at the earliest opportunity. The Good Friday service had that same effect on one other placebo subject, who also had a subsequent psychedelic experience.

The actual experiences of the original psilocybin subjects are best communicated by quoting from, the transcripts of the long-term follow-up interviews. Reverend S.J. had an experience almost uniformly positive. He describes his experience as follows:

> Something extraordinary had taken place which had never taken place before. All of a sudden I felt sort of drawn out into infinity, and all of a sudden I had lost touch with my mind. I felt that I was caught up in the vastness of Creation ... huge, as the mystics say. ... I did experience that kind of classic kind of blending. ... Sometimes you would look up and see the light on the altar and it would just be a blinding sort of light and radiation. ... The main thing about it was a sense of timelessness.
>
> The meditation was going on all during this time, and he [Rev. Howard Thurman] would say things about Jesus and you would have this overwhelming feeling of Jesus. ... It was like you totally penetrated what was being said and it penetrated you. ... Death looked different. It became in focus. ... I got the impression, the sensation ... that what people are essentially in their essence that somehow they would continue to live. They may die in one sense, the physical sense, but their being in heaven would survive. ...
>
> We took such an infinitesimal amount of psilocybin, and yet it connected me to infinity.

Subject L.J. confronted the issue of personal mortality, which he described as follows:

> I was on the floor underneath the chapel pew and he [a group leader] was looking after me and sort of aware of, you know, "L.J. is down there, is everything all right?" I was hearing my uncle who had died [several months before], the one who was a minister, saying, "I want you to die, I want you to die, I want you to die" I could hear his voice saying. The more that I let go and sort of died, the more I felt this eternal life, saying to myself under my breath perhaps, "it has always been this way, it has always been this way. ... O, isn't it wonderful, there's nothing to fear, this is what it means to die, or to taste of eternal life. ..." And the more I died the more I appropriated this sense of eternal life. ... While the service went on I was caught up in this experience of eternal life and appreciating what the peyote Indians or the sacred mushroom Indians experienced with their imbibing of the drug. Just in that one session I think I gained experience I didn't have before and probably could never have gotten from a hundred hours of reading or a thousand hours of reading.
> I would have to say as far as I'm concerned it was a positive, mystical experience ... confirmed by experiences both before and after.

Reverend L.R. had one of the most difficult experiences of all the psilocybin subjects. He described the early portion of his experience as follows:

> Shortly after receiving the capsule, all of a sudden I just wanted to laugh. I began to go into a very strong paranoid experience. And I found it to be scary. The chapel was dark and I hated it in there, just absolutely hated it in there. And I got up and left. I walked down the corridor and there was a guard, a person stationed at the door so individuals wouldn't go out, and he says, "Don't go outside," and I said, "Oh no, I won't. I'll just look outdoors." And I went to the door and out I went. They sent [a group leader] out after me. We [L.R. and the group leader] went back into the building and again, I hated to be in that building and being confined because there were bars on the window and I felt literally like I was in prison. One of the things that was probably happening to me was a reluctance to just flow. I tried to resist that and as soon as resistance sets in there's likely to be conflict and there's likely, I think, for there to be anxiety.

In addition to his emotional struggles, Reverend L.R. discusses the mystical aspect of his experience as follows:

> The inner awareness and feelings I had during the drug experience were the dropping away of the external world and those relationships and then the sudden sense of singleness, oneness. And the rest of normal waking consciousness is really ... illusion. It's not real and somehow that inner

> core experience of oneness is more real and more authentic than normal consciousness. ... I was also experiencing some of those same kind of states that produced anxiety, and I wanted to try to get at the bottom of it.
>
> I personally feel that the experience itself was, and I know his [Pahnke's] research came to the conclusion, that the effect of the chemicals like that is very similar, parallel to, perhaps the same as a classical mystical experience. ...

Reverend Y.M. describes his experience, which also had some difficult moments, as follows:

> I closed my eyes and the visuals were back, the color patterns were back, and it was as if I was in an ocean of bands, streams of color, streaming past me. The colors were brilliant and I could swim down any one of those colors. Then that swirl dissolved itself into a radial pattern, a center margin radial pattern with the colors going out from the center. I was at the center and I could swim out any one of those colors and it would be a whole different life's experience. I could swim out any one of them that I wanted. I mean I could swim metaphorically. There wasn't the sense that I could actually paddle. I could choose any one I wanted, but I had to choose one.
>
> I couldn't decide which one to go out, and eventually it connects to the decision I was in the midst of making about career choices ... when I couldn't decide, I died. Very existential ... for a brief moment there, I was physically dying. My insides were literally being scooped out, and it was very painful. ... I said to myself ... that nobody should have to go through this ... it was excruciating to die like that. Very painful. And I died. ...
>
> After the psilocybin experience, I never consciously made the choice as to what I was going to do career-wise, but the choice was made. It was made while I was on the psilocybin. But it never had to be consciously, intentionally, "Ah, let's see, what I am going to do is. ..." It was made, and I was confident of it, it was going to be. And I did it afterwards. ...

Reverend K.B. describes his mystical experience in the following manner:

> I reel almost whatever I say about it ... is a little bit artificial in terms of describing. What it is is something deeper and probably also more obvious and I think I endeavor to put it into some kind of category which may obscure the point in some way. I remember feeling at the time that I was very unusually incapable of describing it. Words are a familiar environment for me and I usually can think of them, but I didn't find any for this. And I haven't yet.
>
> I closed my eyes, either thinking of meditating or maybe I was drowsy or something. I closed my eyes and it seemed to be darker than usual. And then there was a sudden bolt of light which I think was entirely internal and a feeling almost like a shock or something and that was only for an instant. It wasn't violent but it was a definite tingling like taking hold of a wire or something.
>
> I closed my eyes and ... thought that this would be a fine time for [meditating on the Passion]. ... So I did think about the procession to the cross. And with my eyes closed I had an unusually vivid scene of the procession going by. A scene quite apart from any imagining or anything on my part. A self-actualizing thing-kind of like watching a movie or something, it was apart from me but very vivid.
>
> I had a definite sense of being an infant or being born, or something like that. I had a sense of death, too, but I think actually the sense of death came after the sense of birth. ... I had my hands on my legs and there wasn't any flesh, there were bare bones, resting on my bones. That part wasn't frightening, I was just kind of amazed. ... I think I must have gone along through the life of Christ identifying in a very total sort of way-reliving the life in some way until finally dying and going into the tomb.
>
> I really am glad I took it. And glad that I was a subject. I don't think it would be a particularly memorable experience if I just had listened to the service. I've heard some good services and I

> imagine this was as moving as most. But I think it would be in that category instead of a once-in-a-lifetime sort of thing. ...
>
> I've remained convinced that my ability to perceive things was artificially changed, but the perceptions I had were real as anything else.

Subject T.B. was very comfortable with the effects of the psilocybin, perhaps because he had had mystical experiences prior to the experiment. He describes his experience in the following way:

> I was kneeling there praying and beginning to feel like I was experiencing the kind of prayer life that I experienced back when I was in the seventh grade, eleven or twelve years old. It was the kind of experiences that you knew that something great was happening. I started to go to the root of all being. And discovered that ... you never quite get there. That was my discovery during that time ... it's a philosophy and a theology that I hold yet today. You can approach the fullness of all being in either prayer, or in the psilocybin experience. You can reach out, but you can't dive down ... and hit that root.
>
> The discovery within that experience is that you could approach God by two different ways. You either get to the root, the ground of all being, or the fullness of all being. And in getting to the root, you'll strive, you'll come closer and closer, but it's always half, and you'll think another half step, another half step, and you'll never quite get there. The fullness, to approach the fullness of God is the only way to approach God.

Subject H.R. tells of his largely positive experience in the following way:

> It was a feeling of being ... lifted out of your present state. I just stopped worrying about time and all that kind of stuff ... there was one universal man, personhood, whatever you want to call i t ... a lot of connectedness with everybody and every thing. I don't think Christ or other religious images that I can remember came into it. That's the only reason I didn't think it was religious. I don't remember any religious images. ...
>
> I was convinced after the experiment that I had had quite an experience but that it was really into my psychological depths, and it was not a religious experience. ... It was really the sense that I was discovering the depths of my own self. It did not have a sacredness kind of element to it. ... I didn't think I had experienced a God that was particularly outside of me. What I experienced was a God that was inside of me. And I think that ... made me say, I don't think this is religious, I think this is psychological. But that was because of the way I was defining being ... the way I thought God was being defined by other people at that point.

After the Good Friday experiment, two out of the ten placebo subjects experienced psychedelics. Placebo subject P.J. describes his first psychedelic experience, which took place in a chapel with psilocybin subject L.R. as his guide, as follows:

> I laid on the front pew and watched myself-it seemed like eternity- pour through my navel and totally become nothing. And I felt that this would never stop. It seemed like an eternity of being in heaven and everything. One of the most beautiful experiences in my entire life.
>
> It sure kicks the hell out of one being rigid with what could go on and what kind of experiences you could have. To take one of these drugs says a lot more can happen than what's been happening in your total experience. And I think that's good, and that's why I would want my kids to take it.

Placebo subject L.G. received psilocybin in a hospital as a part of a subsequent experiment conducted by Pahnke (1966) in a fruitless search for a placebo substance which would permit a successful double-blind experiment. L.G. describes his experience as follows:

> It was rather removed from the religious context. Certainly the environment we were in had no

> particular religious symbols. I recall they really stressed [the need to] be absolutely open and just relax and flow with the experience whatever comes. So, there was no context really to suggest a particular experience like there might have been with the Good Friday experiment. We didn't talk about mysticism, as I recall, or religious symbols. ...
>
> At one point I kind of felt like, "Well, maybe this is what it is like to be crazy." I never really panicked but I was acutely aware of anxiety. ... As time evolved I just had this incredible sense of joy and humor, too. I was laughing, real ecstasy. ... The thing that struck me was how anybody could worry or not trust, that just struck me as an absurdity. It was very exciting.
>
> There was an energy, it was almost a sexual thing, an intensity and a joy. The visual things that I experienced and the music, I think were aligned with the sense of unity, everything was unified. We were all part of the same thing. You didn't sense a difference between the music or the physical objects. ...
>
> I think that you can certainly have a religious experience without the religious symbols. Certainly the religious symbols can lead you to a mystical experience. Unfortunately, they can also be divisive. The sectarianism can flow from the different symbols and justify the differences rather than the commonality. I think the mystic experience as I understand it comes down more on the commons.

Contrasting with the desire of two of the control subjects to have their own psychedelic experience, several of the remaining control subjects decided during the course of the experiment that they had no desire to try psychedelics. The behavior of some of their fellow subjects who received psilocybin had frightened them. Placebo subject B.A. remarks:

> I tend to look back on it as an historical curiosity, with intellectual interest to me, but you know, frankly not much else at this point. ... The only change that I can think of that it brought about in my life was a conviction that I never wanted to go on a drug trip of any type ever. And I never have, except for booze. The sights I saw [during the experiment] were very disturbing to me, and I didn't see myself wanting to be in that kind of position. It appeared to he hopelessly out of control and life threatening in several instances.

The remaining control subjects viewed psilocybin with some equanimity but were not motivated enough to seek out their own experience. If the circumstances were right and the substances were legal, several indicated that they might be willing to participate in another experiment.

A Significant Omission

Out of the seven psilocybin subjects formally interviewed, only two had had Good Friday experiences that they reported to be completely positive without significant psychic struggles. The others all felt moments in which they feared they were either going crazy, dying, or were too weak for the ordeal they were experiencing. These struggles were resolved during the course of the Good Friday service and according to the subjects contributed to their learning and growth.

It appears that these difficult moments were significantly underemphasized in Pahnke's thesis and in the subsequent reporting on the experiment. Psilocybin subject H.R. states:

> The other thing I found unique that wasn't talked at all about in what I read, at least in the thesis, was that it was all on the positive up side. I don't know whether other people have said this but I had a down side. ... It was a roller coaster. ... I mean I had a very strong positive sense of the whole ... one with humanity kind of positive glowing, unity kind of feeling and then I went down to the bottom where I was really just ... guilt ... that's all I can say. It was a very, very profound sense of guilt.

Pahnke does mention that two of the subjects who received the psilocybin "had a little difficulty in readjusting to the 'ordinary world' and needed special reassurance by their group leaders until the drug effects subsided"

(Pahnke, 1963, p. 219). Almost certainly, one of those subjects was L.R., who found the chapel to be like a prison and went outside for much of the service. The other subject is, almost certainly, the one who refused to participate in the follow-up study.

In one technical section of the thesis, and in none of his subsequent papers, Pahnke mentions that one of those two subjects later referred to his experience as "a psychotic episode" (Pahnke, 1963, p. 232). In another part of the thesis, Pahnke mentions that injectable thorazine was on hand for emergencies. What he does not report anywhere is that one subject was actually given a shot of thorazine as a tranquilizer during the course of the experiment. Several of the subjects and group leaders remembered this incident and reported in the long-term follow-up interviews that it involved the one psilocybin subject who refused to be interviewed by the author. Needless to say, this occurrence should surely have been mentioned in Pahnke's thesis and, by those few who knew that such an event had actually transpired, in any subsequent reporting on the experiment.

Pahnke probably did not report his use of the tranquilizer because he was fearful of adding to the ammunition of the opponents of the research. Fears that negative aspects of the experiment would be taken out of context and exaggerated may have been justified. In an example of just such a critique, Zaehner asserts in his book, Zen, Drugs and Mysticism, that Pahnke, in an article Pahnke published several years after the Good Friday experiment, repudiated the results of his own study (Zaehner, 1972, p. 105). In that article, Pahnke does indeed say that mystical experiences were absent (Pahnke, 1967, p.71). Pahnke was, however, referring to the control subjects. This misreading of Pahnke by Zaehner is an indication of how, even in an educated scholar, bias can overwhelm facts. This observation, of course, is also true of Pahnke. His silence about his administration of a tranquilizer may perhaps have been good politics; certainly it was bad science.

Although an interview with the subject who was tranquilized would be necessary to understand the subtleties of his experience and its consequences, several long-term follow-up interviews generated second-hand information which may be summarized as follows: This subject was reported to be deeply moved by a sermon delivered by the very dynamic preacher who emphasized that it was the obligation of all Christians to tell people that there was a man on the cross. This subject was reported to have gone outside of the chapel possibly intending to follow the exhortation.

A struggle ensued when the group leaders, worried for his safety, tried to bring him back inside. After a time during which he seemed fearful and was not settling down, Pahnke tranquilized him with a shot of thorazine. He was then brought back into the chapel and remained calm for the duration of the experiment. He participated in all further aspects of the experiment and in the six-month follow-up reported that he considered his fear-experience "slightly harmful" because "in a mob panic-situation I feel I would be less likely to maintain a calm objective position than I might have formerly" (Pahnke, 1963, p. 232).

Subsequent to the Good Friday experiment, the use of tranquilizers in controlled psychedelic psychotherapy research was largely abandoned in favor of simply providing a supportive environment and letting the drug run its course (Richard Yensen, personal communication, 1991).

Discussion

The original Good Friday experiment is one of the preeminent psychedelic experiments in the scientific literature. Despite the methodological shortcomings of the unavoidable failure of the double-blind and the use of several imprecise questions in the questionnaire used to quantify mystical experiences, the experiment's fascinating and provocative conclusions strongly support the hypothesis that psychedelic drugs can help facilitate mystical experiences when used by religiously inclined people in a religious setting. The original experiment also supports the hypothesis that those psilocybin subjects who experienced a full or a partial mystical experience would, after six months, report a substantial amount of positive, and virtually no negative, persisting changes in attitude and behavior.

This long-term follow-up, conducted twenty-four to twenty-seven years after the original experiment, provides further support to the findings of the original experiment. All psilocybin subjects participating in the long-term follow-up, but none of the controls, still considered their original experience to have had genuinely mystical elements and to have made a uniquely valuable contribution to their spiritual lives. The positive changes described by the psilocybin subjects at six months, which in some cases involved basic vocational and value choices and spiritual understandings, had persisted over time and in some cases had deepened. The overwhelmingly positive nature of the reports of the psilocybin subjects are even more remarkable because this long-term follow-up took place during a period of time in the United States when drug abuse was becoming the public's number one social concern, with all the attendant social pressure to deny the value of drug-induced experiences. The long-term follow- up interviews cast considerable doubt on the assertion that mystical experiences catalyzed by drugs are in any way inferior to non-drug mystical experiences in both their immediate content and long-term positive effects, a critique of the Good Friday experiment advanced primarily by Zaehner (Bakalar, 1985).

Unexpectedly, the long-term follow-up also uncovered data that should have been reported in the original thesis. Pahnke failed to report the administration of the tranquilizer thorazine to one of the subjects who received psilocybin. There is no justification for this omission no matter how unfairly the critics of this research may have used the information and no matter how minimal were the negative persisting effects reported by the subject. In addition, Pahnke underemphasized the difficult psychological struggles experienced by most of the psilocybin subjects. These very serious omissions point to an important incompleteness in Pahnke's interpretation of the effects of psilocybin.

Some of the backlash that swept the psychedelics out of the research labs and out of the hands of physicians and therapists can be traced in part to the thousands of cases of people who took psychedelics in non-research settings, were unprepared for the frightening aspects of their psychedelic experiences and ended up in hospital emergency rooms. These unfortunate instances of panic reaction have many causes, yet some of them stem from the way in which the cautionary elements of the Good Friday experiment were inadequately discussed in Pahnke's thesis, in subsequent scholarly reports and in the popular media. For example, Time magazine reported on the experiment in glowing, exaggerated terms stating, "All students who had taken the drug [psilocybin] experienced a mystical consciousness that resembled those described by saints and ascetics" (9/23, 1966, p. 62).

The widespread use of psychedelics, both in medical and nonmedical settings, which began in the 1960s and is still currently taking place, apparently largely underground. Such use was partially founded upon an optimism regarding the inherent safety of the psychedelic experience which did not fully acknowledge the complexity and profundity of the psychological issues associated with psychedelic experiences. With some proponents of psychedelics exaggerating the benefits and minimizing the risks, a backlash against these substances was predictable. With the intriguing connection reported by several psilocybin subjects between mystical experiences and political action, the backlash in retrospect may have been inevitable (Baumeister & Placidi, 1985).

Despite the difficult moments several of the psilocybin subjects passed through, the subjects who participated in the long-term follow-up reported a substantial amount of persisting positive effects and no significant long-term negative effects. Even the subject who was tranquilized in the original experiment reported only "slightly harmful" negative persisting effects at the sixmonth follow-up. Second-hand information gathered during the course of the long-term follow-up suggests that his experience caused no persisting dysfunction and may even have had some beneficial as well as detrimental effects.

The lack of long-term negative effects or dysfunction is not surprising. Strassman's literature review of all controlled scientific experiments using psychedelics in human volunteers found that panic reactions and adverse reactions were extremely rare. He concluded that the potential risks of future research were outweighed by the potential benefits (Strassman, 1984).

This long-term follow-up study, even in light of the new data about the difficulties of the psychedelic experiences of many of the subjects, adds further support to the conclusion that additional studies are justified. Future experiments should be approached cautiously and carefully, with a multidisciplinary team of scientists involved in planning and implementation. Such a team should include psychiatrists, psychologists, religious professionals from a variety of traditions, as well as drug abuse prevention, education and treatment officials. Questions as fundamental as those raised by the Good Friday experiment deserve to be addressed by the scientific community, and pose special challenges to the regulatory agencies. Renewed research can be expected to require patience, courage and wisdom from all concerned.

Recollections of the Good Friday Experiment - Interview with Huston Smith

by

Huston Smith

Interviewed by Thomas B. Roberts Dekalb, Illinois

and

Robert N. Jesse San Francisco, California

T.B.R.: This is October 1, 1996. Huston Smith will be telling us about an event that happened in the Good Friday Experiment in 1962. Huston, do you want to tell us about the student who ran out of the experiment?

Huston Smith: The basic facts of the experiment have been recorded elsewhere and are fairly well known, but I will summarize them briefly. In the early sixties, Walter Pahnke, an M.D. with strong interests in mysticism, wanted to augment his medical knowledge with a doctorate from the Harvard Divinity School (Pahnke, 1963). He had heard that the psychedelics often occasion mystical experiences, so he decided to make that issue the subject of his doctoral research. He obtained the support of Howard Thurman, Dean of Marsh Chapel at Boston University, for his project and also that of Walter Houston Clark who taught psychology of religion at Andover Newton Theological Seminary and shared Wally's [Pahnke] interest in the psychedelics.

Clark procured volunteers from his seminary to engage in an experiment. Howard Thurman's three-hour 1962 Good Friday service at Boston University would be piped down to a small chapel in the basement of the building where the volunteers, augmented by Walter Clark and myself, would participate in it. Half of us would receive, double blind, a dose of psilocybin, and the other half a placebo. The day after the experiment we would all write our accounts of what we had experienced, and Pahnke would have them scored on a scale of from one to ten for the degree to which each subject's experience included the seven traits of mystical experience that W.T. Stace targets in his *Mysticism and Philosophy*. There was one borderline case, but apart from that, the experiences of those who received psilocybin were dramatically more mystical than those in the control group. I was one of those who received the chemical, and I will say a word about my experience before I proceed to the student that you asked about.

The Experiment was powerful for me, and it left a permanent mark on my experiential world view. (I insert the qualifier *experiential* world view to distinguish between the way I *think* and *believe* that the world is, on the one hand, and the way I usually experience it to be.) For as long as I can remember, I have believed in God, and I have frequently experienced his presence in beauty, in nature, and (less frequently) in the clear light of the void that mystics speak of. But until the Good Friday Experiment, 1 had had no direct personal encounter with Him/Her/It of the sort that *bhakti* yogis, Pentecostals, and born-again Christians describe. The Good Friday Experiment changed that, presumably because the service focused on God as incarnated in Christ.

For me the climax of the three-hour service came during a solo that was sung by a soprano whose voice, through the prism of psilocybin, I can only describe as angelic. What she sang was no more than a simple hymn, but it entered my soul so deeply that its opening and closing verses have stayed with me ever since.

> My times are in Thy hand, my God, I wish them there;
> My life, my friends, my soul, I leave, entirely to Thy care.
>
> My times are in Thy hands, I'll always trust in Thee;
> And after death at Thy right hand I shall forever be.

In broad daylight those lines are not at all remarkable, but in the context of the Experiment, as there sung, they said everything. The last three measures of each stanza ascended to a dominant seventh which the concluding tonic then resolved. This is as trite a way to end a melody as exists, but the context changed that totally. My mother was a music teacher and instilled in me an acute sensitivity to harmonic progressions. When that talent and my Christian nurturance converged on the Good Friday story under psilocybin, the gestalt transformed the routine musical progression of that hymn into the most powerful cosmic homecoming I have ever experienced.

There is a second reason for gratitude to the Good Friday Experiment: it rounded out my experience of God's nature. *Jnanic* by nature, I had had (as I have noted) a number of powerful transpersonal experiences of God, but I had not strongly experienced his personal side. The Good Friday Experiment changed that. Since that momentous afternoon, I know firsthand what *bhaktis* are talking about when they speak:of their personal, loving relationship with God. All of this is a long prelude to the student who ran out of the experiment, which is what you asked about, but a knowledge of the context helps us understand the episode, I think.

As the chemical came over me, I began to be aware of a mounting disorder in the chapel. After all, half of our number were in a condition where social decorum meant nothing, and the other half were more interested in the spectacle that was unfolding than in the service proper. They were not above commenting on the spectacle and even joking about it among themselves. Afterwards a number of them confessed that feelings of being cheated of the experience helped fuel their quips.

In any case, from out of this bizarre mix, one of our number emerged. He arose from his pew, walked up the aisle, and with uncertain steps mounted the chapel's modest pulpit. Thumbing through its Bible for a few moments, he then mumbled a brief incoherent homily, blessed the congregation with the sign of the cross, and started back down the aisle. But instead of returning to his pew, he marched to the rear entrance of the chapel and exited.

Now, before the experiment began, each of us had been paired with a partner in the buddy system. We knew that one member in each pair would receive psilocybin and were instructed that the other member should look after his partner if the need arose. I was not "John's" partner - but no one else followed him out of the chapel, so I did.

This introduces an interesting parenthetical point. More than once I have been struck by the fact, widely corroborated, that however far one may be into the psychedelic experience (short of the dissociation that John was experiencing), if the need arises to snap back to normal, one has no problem doing so. So it was in this case. When John's buddy didn't respond to his leaving the chapel, I sprang to my feet and followed him out.

He had made a right turn and was striding down the hall, but we had been told that the entire basement had been sealed off for the experiment, so I was not overly concerned. But when he reached the door at the end of the corridor and jammed down its latch bar, it swung open. Something had misfired in the instructions to the janitor, and my charge, zonked out of his skull, was at large on Commonwealth Avenue. I ran after him, but my urgings to return to the chapel fell on deaf ears, and he shook off my grip on his elbow as if it were cobwebs.

What to do? I was afraid to leave him lest I lose track of him, but alone I was powerless to dissuade him from what appears to be a determined mission.

Providentially, help arrived from an unexpected quarter. The wife of someone: involved in the study was having a picnic on the grass with their child, and I shouted to her to keep track of John while I rushed back to the chapel for help. The strategy worked. When I returned on the double with Wally and another accomplice, John was still visible a block and a half ahead. Before we reached him, we saw him enter what turned out to be 745 Commonwealth Avenue, the building that houses Boston University's School of Theology and parts of its College of Liberal Arts. We caught up with him on the stairs to the third floor, but Wally's remonstrances cut no more ice than mine had. Together, however, the three of us were able to block his further ascent.

Things were at a standstill when a postman rounded the corner of the steps from below. He was carrying a brown envelope copiously plastered with special delivery stickers, and as he was passing us, John's arm shot out and snatched it from him. I was too occupied to notice the expression on the postman's face, for two of us had all we could do pinning John's arms while, finger by finger, Wally pried the crumpled envelope from John's vice-like grip and returned it to its stunned carrier. I have often wondered how that postman explained the mangled condition of his packet to its recipient, and how he described the incident to his wife at dinner that evening.

The rest is simply told. Realizing that he was overpowered - barely, for under the influence his strength was like Samson's - John, tightly flanked, submitted to being walked back to the chapel where Wally injected an antidote. Immediately he was back in his right mind but with total amnesia as to what had occurred.

It took twenty-four hours for all the pieces of the episode to come back to him and be fitted into place. God, it turned out, had chosen him to announce to the world the dawning millennium of peace and good will. (As often happens in such cases, the actual wording of the message made little sense to normal ears.) In his homily in the chapel, John broke the news to our congregation, but he needed to get it to the world at large, which was what caused him to leave the chapel. When, walking down Commonwealth Avenue, he saw the plaque announcing "Dean of the College of Liberal Arts" by the entrance to 745 Commonwealth Avenue, it occurred to him that deans have influence, so if he could get to that dean, that dean would call a press conference that would complete John's mission. The postman's packet was for the dean, he felt sure, so if he attached himself to it, it would take him to his targeted dean.

John's long-term feelings about the experiment were heavily negative. He was the only one of its subjects who refused to participate in Rick Doblin's twenty-fifth-year retrospective study of the long-term effects of the Experiment on its subjects and threatened to sue if his name was included (Doblin, 1991).

T.B.R.: Was there something in Howard Thurman's sermon that made him feel he should spread the message or be messianic or prophetic?

H.S.: Not that I noticed. It was a typical Good Friday service with meditations on the seven last words of Christ. Howard Thurman was very good, a spiritual genius, and even without psychedelics, he could move people. People were moved spiritually, uplifted by him, but I don't remember the content of Howard Thurman's words, only their moving impact. Did you ever meet him?

T.B.R.: No. I'd like to have heard him.

HS.: Just recounting this and getting my mind back into that afternoon makes my spine tingle.

T.B.R.: Are there other memories of the afternoon that come to mind?

H.S.: I remember that at times a hubbub seemed to erupt in our small chapel. I was too deep into my own experience for it to distract me, but I was peripherally aware of it and realize now, in retrospect, that a spectator would probably have found us a pretty unruly bunch. After all, half of us were stoned to the point where decorum meant nothing, and the other half - as I learned from several of them the next day - were resentful at having been left out and were not above acting out their resentment in derisive laughter and incredulous hoots at the way the rest of us were behaving.

I also remember a short exchange with one of the subjects in the foyer to the chapel just before the service began. Our doses had been administered an hour before noon, and, already under the influence of my psilocybin and sensing (wrongly, as it turned out) that he was as well, I said to him from the depths of my being, "It's true, isn't it?" He didn't respond and told me a day or two later that he had gotten only a placebo and hadn't a clue as to what the "it" that I had reverentially alluded to was all about. I think of that when I hear people claim that acid enables you to read minds. I couldn't have been more wrong in my surmise as to where things stood with him.

T.B.R.: Anything else?

H.S. Only the renewed gratitude to Wally Pahnke and his Experiment that our conversation has awakened in me. As I noted toward the beginning of our conversation, what his Experiment did for me was to round out my experience of the holy by enabling me to experience it in a personal mode, not just abstractly - a questionable word here - in music and nature and (more rarely) in the clear light of the void. Because Good Friday centers on God incarnated in a person, Christ, in that setting I experienced (for the first time powerfully) the divine in that mode. Spirit responding to Spirit, deep to deep, in the classic, dualist mode of *bhakti* yogis. This permanently enlarged my experiential toolbox. My first psychedelic experience was neoplatonically monistic; this one was personal and relational. So ever since then I have been able to understand experientially that classic mode of mysticism.

T.B.R.: When was your first, monistic experience?

H.S. New Year's Day, 1961, with Timothy Leary in his home in Newtonville.

T.B.R.: What about carryover from your Good Friday experience? Did it change you?

H.S.: Who knows? As a psychologist, you know better than I do that behavior change is one of the hardest things to measure. Staying off the bottle, or out of jail, for example, seem to be the only objective criteria we have. Subjectively, all of my three or four important experiences left me feeling that I was a better person. And I think that actually, in each case, I was more slowed down, sensitive, attuned to the moment, considerate toward others, and aware of life's wonder and mystery. For a few days, I must immediately add, however, for sooner or later the everyday world always reclaimed me. All I can say is that following the Good Friday Experiment, its spell lasted longer. It was more like three months than three weeks or three days.

T.B.R.: Walter Houston Clark reported the same thing - that he too felt that he was a better person. More considerate of family and friends.

Thank you, Huston, for filling us in on an important part of the Good Friday Experiment not previously recorded.

Abstract

Psilocybin has been used for centuries for religious purposes; however, little is known scientifically about its long-term effects. We previously reported the effects of a double-blind study evaluating the psychological effects of a high psilocybin dose. This report presents the 14-month follow-up and examines the relationship of the follow-up results to data obtained at screening and on drug session days. Participants were 36 hallucinogen-naïve adults reporting regular participation in religious/ spiritual activities. Oral psilocybin (30 mg/70 kg) was administered on one of two or three sessions, with methylphenidate (40 mg/70 kg) administered on the other session(s). During sessions, volunteers were encouraged to close their eyes and direct their attention inward. At the 14-month follow-up, 58% and 67%, respectively, of volunteers rated the psilocybin-occasioned experience as being among the five most personally meaningful and among the five most spiritually significant experiences of their lives; 64% indicated that the experience increased well-being or life satisfaction; 58% met criteria for having had a 'complete' mystical experience. Correlation and regression analyses indicated a central role of the mystical experience assessed on the session day in the high ratings of personal meaning and spiritual significance at follow-up. Of the measures of personality, affect, quality of life and spirituality assessed across the study, only a scale measuring mystical experience showed a difference from screening. When administered under supportive conditions, psilocybin occasioned experiences similar to spontaneously occurring mystical experiences that, at 14-month follow-up, were considered by volunteers to be among the most personally meaningful and spiritually significant of their lives.

Key words: entheogen; hallucinogen; humans; mystical experience; psilocybin; psychedelic; religion; spiritual

Introduction

Although many have anecdotally claimed that psilocybin, the principal psychoactive component of various hallucinogenic mushroom species, can facilitate experiences providing sustained, positively valued impact, little is known scientifically about such effects. Psilocybin has been used as a sacrament for centuries, possibly millennia, in structured religious ceremonies (Wasson, 1980; Stamets, 1996; Metzner, 2004). Like other classical hallucinogens [*d*-lysergic acid diethylamide (LSD), mescaline, *N*,*N*-dimethyltyrptamine (DMT)], the effects of psilocybin are primarily mediated at 5-HT$_{2A}$ receptor sites (Nichols, 2004), and the acute subjective effects include robust changes in perception, cognition, affect, volition and somaesthesia (Isbell, 1959; Wolbach, *et al*., 1962; Rosenberg, *et al*., 1964).

The degree to which responses to psilocybin are influenced by nonpharmacological variables was not understood by early researchers (e.g. Isbell, 1959; Malitz, *et al*., 1960; Rinkel, *et al*., 1960; Hollister, 1961). By providing more preparation and interpersonal support during drug action, subsequent research described more positively valued experiences and fewer adverse effects (e.g. panic and paranoia) (Chwelos, *et al*., 1959; Leary, *et al*., 1963; Metzner, *et al*., 1965; Pahnke, 1969). In response to the hallucinogen abuse of the 1960s, human hallucinogen research largely ceased and has only recently resumed. Notably, Vollenweider and colleagues in Switzerland and Gouzoulis-Mayfrank and colleagues in Germany have studied the neurocognitive, perceptual and psychosis-mimicking effects of psilocybin (e.g. Vollenweider, *et al*., 1998; Gouzoulis- Mayfrank, *et al*., 1999; Hasler, *et al*., 2004; Carter, *et al*., 2005, 2007).

Recently, we used rigorous double-blind methods to evaluate the acute (7 h) and longer term (2 months) psychological effects of a high dose of psilocybin (30 mg/70 kg) relative to an active comparison compound (40 mg/70 kg methylphenidate) in 36 hallucinogen-naïve volunteers (Griffiths, *et al*., 2006). In contrast to the aforementioned recent psilocybin studies, the study optimized the potential for positively valued experiences by providing 8 h of preparation and by instructing volunteers to focus explicitly on the phenomenology of the drug experience rather than perform tasks. The results showed psilocybin to occasion experiences with substantial personal meaning and spiritual significance when evaluated 2 months after psilocybin. We have subsequently conducted a follow-up study evaluating effects at 14 months after their last drug session. Volunteers completed questionnaires that assessed personality, affect, quality of life, spiritual experience, and persisting changes in attitude and behaviour attributed to the blinded psilocybin session. This report analyses these 14-month follow-up results and the contribution of baseline characteristics and immediate drug effects to long-term persisting effects.

Methods

Participants

Participants were recruited through flyers announcing a study of states of consciousness brought about by a naturally occurring psychoactive substance used sacramentally in some cultures. The 36 study participants were medically and psychiatrically healthy and without histories of hallucinogen use. Sixteen participants were males [incorrectly reported as 14 in the previous publication (Griffiths, *et al.*, 2006)]. Participants had an average age of 46 years (range 24-64); 97% were college graduates and 56% had post-graduate degrees. All were employed full- or part-time. Fifty-three per cent indicated affiliation with a religious or spiritual community, such as a church, synagogue or meditation group. All volunteers indicated at least intermittent participation in religious or spiritual activities, such as religious services, prayer, meditation or study groups. Volunteers did not receive monetary compensation for participation. Additional information about participant recruitment and demographics has been described previously (Griffiths, *et al.*, 2006).

Study design

The study compared the effects of orally administered psilocybin (30 mg/70 kg) and methylphenidate hydrochloride (40 mg/70 kg) using a double-blind design that involved two or three 8-h drug sessions conducted at 2-month intervals. Thirty-six volunteers were randomly assigned to receive either two sessions ($n = 30$) or three sessions ($n = 6$). The volunteers who received two sessions were then randomly assigned to receive psilocybin or methylphenidate on the first session (15 per group), with the alternative drug administered on the second session. The third group ($n = 6$) received methylphenidate on the first two sessions and unblinded psilocybin on the third session. The purpose of having the possibility of a third session was to help control for expectancy effects (Griffiths, *et al.*, 2006).

Preparation and drug session procedures

Participants and monitors were informed that participants would have either two or three sessions, that in at least one session they would receive a moderate or high dose of psilocybin, and that an inactive placebo, a low dose of psilocybin, or various other drugs could be administered in the other session(s). Participants and monitors were unblinded to drug conditions after all participants had completed the 14-month follow-up. The primary monitor met with each volunteer on four occasions before the first session to develop rapport and trust.

The 8-h drug sessions were conducted in a living room-like environment. During the session, two monitors were present with a single participant. Participants were encouraged to focus their attention inward by lying down on the couch and wearing an eye mask and headphones through which a programme of classical music was played. Additional details of instructions to volunteers, volunteer-monitor meetings before and after sessions, and outcome measures have been described previously (Griffiths, *et al.*, 2006).

Measures of personality, affect, quality of life and spirituality assessed at screening, 2 months after each session, and at the 14-month follow-up

The following instruments were assessed: NEO Personality Inventory (NEO PI-R) (Costa and McCrae, 1992); Positive and Negative Affect Scale - Expanded Form (PANAS-X) for how one feels generally (Watson and Clark, 1994); Quality of Life Inventory raw score (Frisch, 1994); Measure of Actualization Potential (Leclerc, *et al.*, 1999); Mysticism Scale (described below); Spiritual Transcendence Scale (Piedmont, 1999, 2007); Faith

Maturity Scale - 12 item version (Benson, *et al.*, 1993); Functional Assessment of Chronic Illness Therapy - Non-Illness - Spiritual Well-Being Scale (FACITSp-NI-12) (Peterman, *et al.*, 2002).

Measures assessed throughout the session

At 0.5-6 h after capsule administration, monitors rated several dimensions of participant behaviour and mood, including a rating of the overall drug effect on a 5-point scale from 0 = none to 4 = extreme. Data were the mean of the two monitors peak scores (i.e. the maximum value from 0.5 to 6 h after capsule administration for each monitor).

Measures assessed 7 h after drug administration

When the major drug effects had subsided, the participant completed two questionnaires assessing subjective drug effects: Hallucinogen Rating Scale (HRS) (Strassman, *et al.*, 1994) and APZ (assessing altered states of consciousness) (Dittrich, 1998).

Participants also completed two questionnaires assessing mystical experience. The Mysticism Scale (9-point version) has been extensively studied, demonstrates cross-cultural generalizability, and is well-regarded in the psychology of religion (Hood, *et al.*, 2001; Spilka, *et al.*, 2003). When administered 7 h after drug administration, participants were instructed to complete the questionnaire with reference to their experiences since they received the capsules that morning. For the lifetime version of the questionnaire, participants were instructed to answer with reference to their total life experiences.

As part of the States of Consciousness Questionnaire, volunteers completed the Pahnke-Richards Mystical Experience Questionnaire (Griffiths, *et al.*, 2006), which assesses seven domains of mystical experiences: internal unity (pure awareness; a merging with ultimate reality); external unity (unity of all things; all things are alive; all is one); transcendence of time and space, ineffability and paradoxicality (claim of difficulty in describing the experience in words); sense of sacredness (awe); noetic quality (claim of intuitive knowledge of ultimate reality) and deeply felt positive mood (joy, peace, love). Ratings were made on a 6-point scale relative to the participant's overall life experience. Data on each scale were expressed as a proportion of the maximum possible score. A mean total score was calculated as the mean of the following six domains: unity (either internal or external, whichever was greater), transcendence of time and space, ineffability, sense of sacredness, noetic quality and positive mood. Based on prior research (Pahnke, 1969; Griffiths, *et al.*, 2006), criteria for designating a volunteer as having had a 'complete' mystical experience were that scores on each of the six domains were ≥0.6.

Measures assessed two months post-session

For this assessment, participants completed the previously described standardized measures and the Persisting Effects Questionnaire, a measure of changes in attitudes, mood, and social and other behaviours (Griffiths, *et al.*, 2006). The questionnaire also included three questions: (I) How personally meaningful was the experience? (1, no more than routine, everyday experiences; 2, similar to meaningful experiences that occur on average once or more a week; 3, similar to meaningful experiences that occur on average once a month; 4, similar to meaningful experiences that occur on average once a year; 5, similar to meaningful experiences that occur on average once every 5 years; 6, among the 10 most meaningful experiences of my life; 7, among the five most meaningful experiences of my life; 8, the single most meaningful experience of my life); (II) Indicate the degree to which the experience was spiritually significant to you? (1, not at all; 2, slightly; 3, moderately; 4, very much; 5, among the five most spiritually significant experiences of my life; 6, the single most spiritually significant experience of my life) and (III) Do you believe that the experience and your contemplation of that experience have led to change in your current sense of personal well-being or life satisfaction? (rated from +3 = increased very much to -3 = decreased very much). This questionnaire was developed after the initiation of the study and was completed by 29 of the 36 participants (approximately the same per cent within all three groups).

14-month follow-up

This assessment was conducted 14 months after the last session, which was 16 months after the psilocybin session in volunteers who received psilocybin in session 1, and 14 months after psilocybin in volunteers who received psilocybin in sessions 2 or 3. For this assessment, all 36 participants completed the Retrospective Questionnaire as well as the previously described standardized measures. At this same time, volunteers participated in an open-ended clinical interview reflecting on study experiences and current life situation.

For purposes of completing the Retrospective Questionnaire, volunteers were first asked to identify on which session they experienced the 'most pronounced changes in your ordinary mental processes'. All but one volunteer identified the psilocybin session. That volunteer, who reported having unusual experiences during both sessions, was asked to complete the questionnaire with regard to the psilocybin session. The remaining volunteers completed the questionnaire in reference to the identified session.

Forty-three items in this questionnaire comprised the previously described Pahnke-Richards Mystical Experience Questionnaire, which was completed looking back on the session and rating the degree to which various phenomena were experienced during the session. The rationale for reassessing these ratings at the 14-month follow-up was that the ratings were made relative to the participant's overall life experience, which could have changed over the intervening follow-up period. Eighty-nine items comprised the previously described Persisting Effects Questionnaire. For these items, volunteers were asked to rate any current persisting effects that they attribute to the experience. Within the Retrospective Questionnaire, volunteers were also asked to provide written descriptions of what was most memorable and what was most spiritually significant about the experience.

Statistical analysis

Inspection of the data indicated that the results from the 30 subjects, who received each drug once, were similar to results from the six subjects, who received methylphenidate twice followed by psilocybin once. Therefore, data from all 36 subjects are analysed below. Data from the first methylphenidate session were used for the six, who received it twice.

To characterize the study sample on measures of personality, affect, quality of life and spirituality relative to the general population, individual subject data at screening were converted to T-scores using norms for: the five factors of the NEO PI-R (Costa and McCrae, 1992); the Positive and Negative Affect factors of the PANAS-X (Watson and Clark, 1994); raw score on the Quality of Life Inventory (Frisch, 1994); the overall mean on the Measure of Actualization Potential (Leclerc, *et al.*, 1999); total score on the Mysticism Scale-Lifetime (Hood and Williamson 2000; Ralph W. Hood Jr, 2007, personal communication) and total score of the Spiritual Transcendence Scale (Ralph L. Piedmont, 2007, personal communication). *T*-scores below 45 or above 55 were considered low or high, respectively, on that dimension.

Repeated measures analysis of variance (ANOVA) was conducted to examine changes in the measures of personality, affect, quality of life and spirituality that were assessed at screening, 2 months after the psilocybin session, and 14 months after the last session ($N = 36$). Bonferroni-corrected *t*-tests were used to assess differences among the three time-points. ANOVA with Bonferroni-corrected *t*-tests were also conducted with the Persisting Effects Questionnaire data ($n = 29$) assessed at 2 months post-methylphenidate and post-psilocybin, and again retrospectively for psilocybin at the 14-month followup, and with the Pahnke-Richards Mystical Experience Questionnaire data ($N = 36$) assessed 7 h post-methylphenidate and post-psilocybin, and again retrospectively for psilocybin at the 14-month follow-up.

To examine differences in the proportion of subjects endorsing specific answers on the Persisting Effects Questionnaire, *z*-tests of proportions compared data at 2 months post-methylphenidate, 2 months post-psilocybin and again retrospectively for psilocybin at the 14-month follow-up. For ratings of personally meaningful and spiritually significant, endorsement was defined as rating either 'among the top 5' or 'the single most'. For ratings of increased well-being or life satisfaction, endorsement was defined as rating 'increased moderately' or 'increased very much'. For ratings of positive behavioural change, endorsement was defined as rating 'moderate', 'strong' or 'extreme'.

Pearson's correlations were calculated to examine the relationships between: (1) volunteer's ratings of personal meaning and spiritual significance at the 14-month follow-up and (2) the following screening measures: scores on the five factor subscales of the NEO PI-R, total scores on the Mysticism Scale, Spiritual Transcendence Scale, Faith Maturity Scale, and FACIT-Sp-NI, and mean overall score on the Measure of Actualization Potential Questionnaire.

Pearson's correlations were calculated between: (1) volunteer's ratings of personal meaning and spiritual significance at the 14-month follow-up and (2) data obtained on the psilocybin session day. The psilocybin session data used for these calculations were: peak monitor ratings of six dimensions of participant's behaviour during sessions (overall drug effect, anxiety or fearfulness, distance from ordinary reality, tearing/crying, joy/intense happiness, and peace/harmony); the six subscales of the HRS; the three subscales of the APZ questionnaire; total scores on the post-session Mysticism Scale and mean score on the post-session Pahnke-Richards Mystical Experience Questionnaire. The follow-up data used for these calculations were the volunteer ratings of personal meaning and spiritual significance attributed to the psilocybin session experience.

Significant correlations between the total scores on the Mysticism Scale and follow-up measures of personal meaning or spiritual significance were further examined using a multiple regression model to control for any confounding by intensity of drug effect. Three separate measures of drug effect intensity were examined: peak monitor ratings of overall drug effect; subject-rated intensity as measured by the Intensity subscale of the HRS and subject-rated intensity from the single item rating 'Intensity' in the HRS. In separate analyses for each intensity measure, the intensity measure was entered into the regression first and the post-session Mysticism Scale score was entered second to assess its effect on the follow-up measures independently of intensity.

For statistical tests, $p < 0.05$ was considered significant except for correlations (for which a more conservative $p < 0.01$ was used) and for the Bonferroni-corrected *t*-tests.

Results

Measures of personality, affect, quality of life and spirituality assessed at screening, 2 months after the psilocybin session, and at the 14-month follow-up

The measures of personality, affect, quality of life, and spirituality assessed at screening indicated that the volunteers were generally well-adjusted, outgoing, open and high in spirituality. More specifically, relative to adult norms, the mean *T*-score for the group of volunteers on the NEO PI-R were low on Neuroticism (*T*-score, 41.8) and high on Extroversion, Openness, and Agreeableness (55.3, 65.7, and 55.7 respectively); low on Negative Affect on the PANAS-X (44.4); and high on the Measure of Actualization Potential (59.2), Mysticism Scale-Lifetime (55.6), and Spiritual Transcendence Scale (63.1).

Of the eight questionnaires assessed, only the Mysticism Scale-Lifetime showed significant changes across the study. For the Mysticism Scale-Lifetime, the total score (Figure 1) and the scores on each of the three factors (Interpretation, Introvertive Mysticism, and Extrovertive Mysticism) were significantly greater than screening at both the 2-month and 14-month assessments.

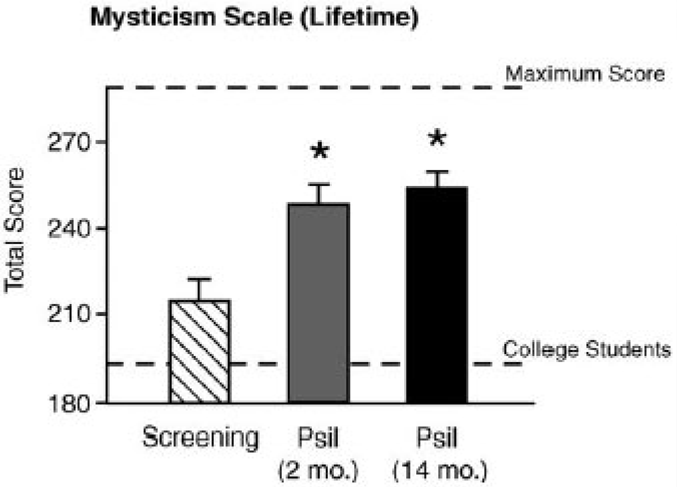

Figure 1. Total score on lifetime version of the Mysticism Scale at screening, 2 months following psilocybin, and at the 14-month follow-up. Bars are mean scores with brackets showing 1 SEM (N = 36). Asterisks show significant differences from the screening assessment. For comparison, lower dashed line shows mean score for college students (Hood, *et al*., 2001; Ralph W. Hood Jr, 2007, personal communication); upper dashed line show maximum possible score.

Pahnke-Richards Mystical Experience Questionnaire assessed immediately after sessions and at the 14-month follow-up

The psilocybin session experience, when rated immediately post-session and when rated retrospectively at the 14-month follow-up, produced significant elevations compared with the methylphenidate experience in each of seven domains of mystical experience and the mean total score on the Pahnke-Richards Mystical Experience Questionnaire (Table 1). The 14-month retrospective rating for psilocybin did not differ significantly from the immediate post-session rating. Based on *a priori* criteria, 22 of the 36 volunteers had a 'complete' mystical experience based on immediate post-session ratings; at follow-up, 21 volunteers continued to fulfil these criteria.

Table 1. Volunteer Ratings on the Pahnke-Richards Mystical Experience Questionnaire section of the State of Consciousness Questionnaire completed at the end of methylphenidate and psilocybin sessions, and again retrospectively for psilocybin at the 14-month follow-up[a]

Scale description	Methylphenidate (post-session)[b] (*N* = 36)	Psilocybin (post-session) (*N* = 36)	Psilocybin (14 months) (*N* = 36)
Internal unity	0.26 (0.04)	0.73 (0.05)*	0.71 (0.05)*
External unity	0.22 (0.04)	0.64 (0.05)*	0.67 (0.05)*
Sacredness	0.38 (0.04)	0.80 (0.04)*	0.78 (0.04)*
Intuitive knowledge	0.32 (0.05)	0.74 (0.05)*	0.73 (0.04)*
Transcendence of time and space	0.27 (0.04)	0.75 (0.04)*	0.75 (0.04)*
Deeply felt positive mood	0.39 (0.04)	0.75 (0.04)*	0.70 (0.05)*
Ineffability and paradoxicality	0.33 (0.04)	0.80 (0.04)*	0.78 (0.05)*
Mean total score	0.33 (0.04)	0.76 (0.04)*	0.75 (0.04)*

[a] Data were mean scores with 1 SEM shown in parentheses; data were expressed as a proportion of the maximum possible score.
[b] For the six subjects, who received methylphenidate on two sessions, the data were from the first session.
*Significant difference from the post-methylphenidate condition ($P < 0.05$); there were no significant differences between the psilocybin post-session condition and the psilocybin 14-month follow-up.

Measures of persisting effects assessed 2 months after drug sessions and at the 14-month follow-up

Compared with methylphenidate, the psilocybin session experience produced significant increases in ratings of positive attitudes, mood, social effects and behaviour when rated retrospectively at both 2 months and at the 14-month follow-up (Table 2). The ratings at the 14-month follow-up did not differ significantly from those at 2 months. The ratings of negative changes on these same dimensions were very low and not significantly different across conditions.

Table 2. Volunteer ratings on the Persisting Effects Questionnaire completed 2 months following the methylphenidate and psilocybin sessions, and again retrospectively for psilocybin at the 14-month follow-up[a,b]

Scale or question description	Methylphenidate (2 months) (*n* = 29)[c]	Psilocybin (2 months) (*n* = 29)	Psilocybin (14 months) (*n* = 29)	Psilocybin (14 months) (*n* = 36)[d]
Positive attitudes about life and/or self	23.4 (4.0)	53.1 (4.6)*	53.5 (5.4)*	53.6 (4.7)
Negative attitudes about life and/or self	0.3 (0.1)	0.6 (0.3)	0.5 (0.3)	0.7 (0.3)
Positive mood changes	16.6 (3.1)	37.4 (4.7)*	36.0 (5.5)*	37.9 (4.8)
Negative mood changes	0.5 (0.4)	1.4 (0.6)	1.6 (0.9)	1.7 (0.8)
Altruistic/positive social effects	19.0 (4.1)	44.5 (5.3)*	45.5 (6.3)*	46.3 (5.4)
Antisocial/negative social effects	0.3 (0.2)	0.7 (0.4)	0.7 (0.4)	0.6 (0.4)
Positive behaviour changes	29.7 (6.1)	56.6 (5.0)*	58.3 (5.4)*	58.1 (4.9)
Negative behaviour changes	1.4 (1.0)	0.0 (0)	0.7 (0.7)	0.6 (0.6)
How personally meaningful was the experience?	3.6 (0.3)	6.4 (0.2)*	6.3 (0.3)*	6.1 (0.2)
How spiritually significant was the experience?	2.7 (0.2)	4.8 (0.2)*	4.5 (0.3)*	4.5 (0.2)
Did the experience change your sense of well-being or life satisfaction?	+0.9 (0.2)	+1.9 (0.2)*	+1.9 (0.2)*	+1.8 (0.2)

[a] Data were mean ratings with 1 SEM shown in parentheses.

[b] Data on attitudes, mood, social, and behaviour changes were expressed as percentage of maximum possible score; data for the three questions were raw scores.

[c] For the five subjects who received methylphenidate on two sessions and who completed this questionnaire, the data are from the first session.

[d] Data for the full group of 36 were not available for the 2-month assessments, but is presented here for comparison.

*Significant difference from methylphenidate 2-month assessment ($p < 0.0001$); there were no significant differences between the psilocybin 2-month condition and the psilocybin 14-month follow-up (*n* = 29).

Table 2 also shows that the psilocybin session was associated with significant increases in ratings of the personal meaning of the experience, the spiritual significance of the experience, and well-being or life satisfaction due to the experience. No volunteer rated the experience as having decreased his or her sense of well-being or life satisfaction at either 2 months or the 14-month follow-up. Figure 2 shows ratings from these three questions plus a question on positive behaviour change expressed as the percentage of the participants endorsing specific answers. Even at the 14-month follow-up, 58% of 36 volunteers rated the experience on the psilocybin session as among the five most personally meaningful experiences of their lives and 67% rated it among the five most spiritually significant experiences of their lives, with 11% and 17%, respectively, indicating that it was the single most meaningful experience, and the single most spiritually significant experience. Furthermore, 64% of the 36 volunteers indicated that the psilocybin session experience increased their sense of well-being or life satisfaction either moderately or very much, and 61% rated that the experience was associated with moderate to extreme positive behaviour change.

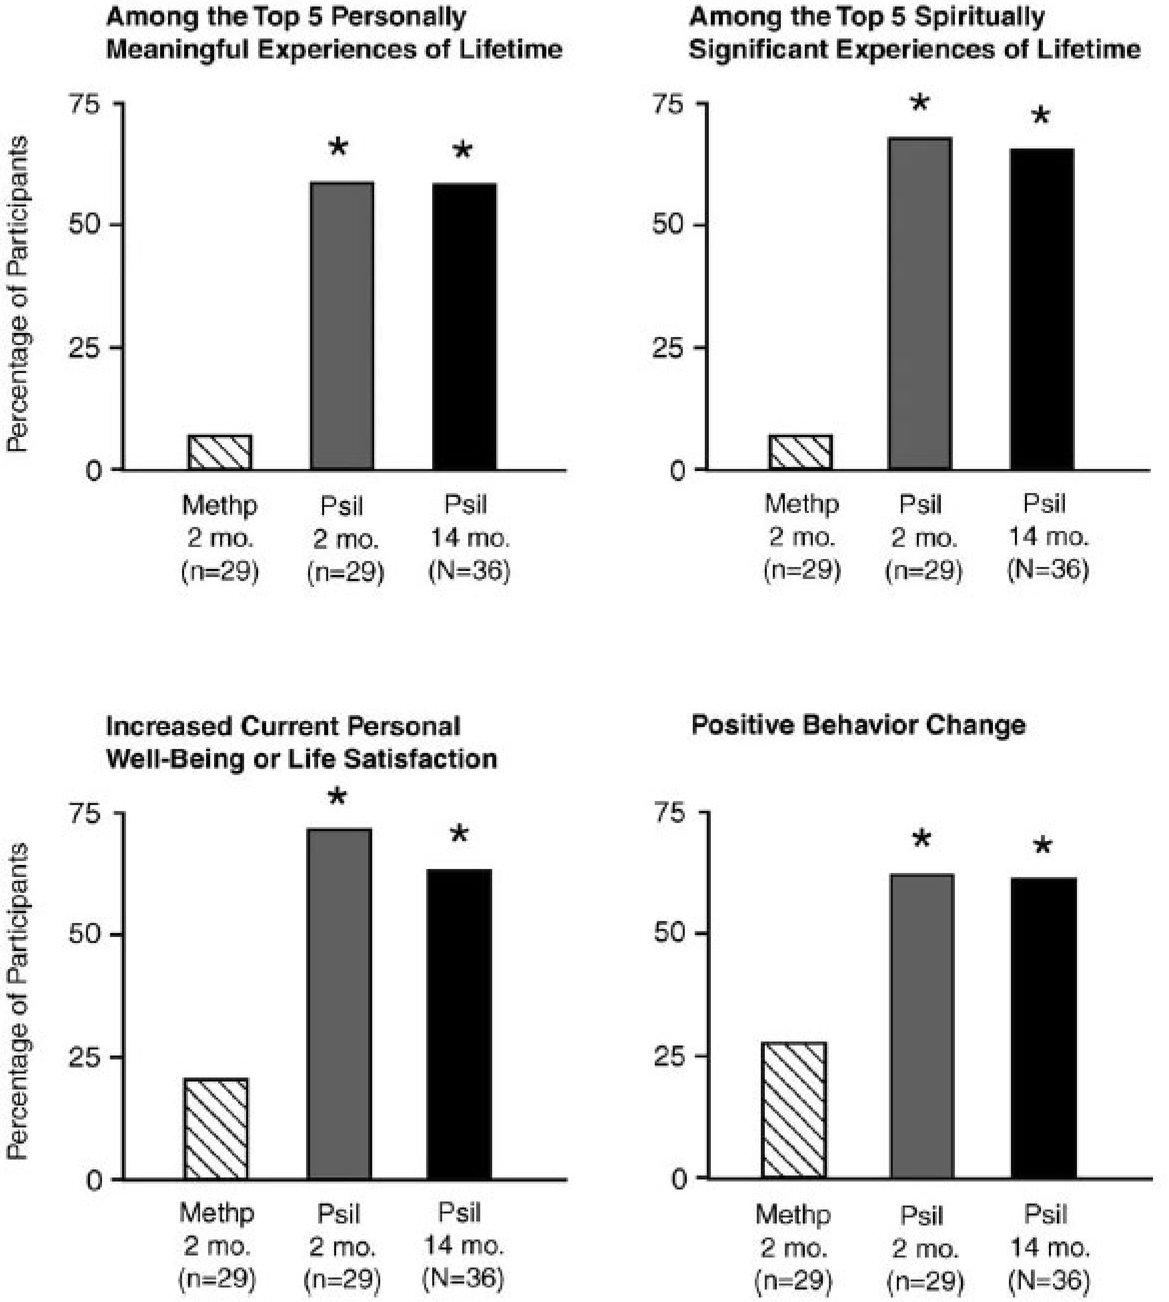

Figure 2. Percentage of volunteers endorsing specific answers on the Persisting Effects Questionnaire completed 2 months following the methylphenidate (Methp) and psilocybin (Psil) sessions (*n* = 29), and again retrospectively for psilocybin at the 14-month follow-up (*N* = 36). For ratings of personally meaningful and spiritually significant (top two panels), the data are the percentage rating 'among the top 5' or 'the single most'. For ratings of increased well-being or life satisfaction, the data were the percentage rating 'increased moderately' or 'increased very much'. For ratings of positive behavioural change, the data were the percentage rating 'moderate', 'strong' or 'extreme'. Asterisks show significant differences ($p < 0.05$, *z*-test of proportions, *n* = 29 at each assessment) from the methylphenidate 2-month assessment; there were no significant differences between the psilocybin 2-month condition and the psilocybin 14-month follow-up assessment. For the methylphenidate results, the data presented are from the first methylphenidate session for the five subjects who received methylphenidate on two sessions and who completed this questionnaire.

Relationships between screening data and the 14-month follow-up data on volunteer ratings of personal meaning and spiritual significance

Because attribution at follow-up of sustained high personal meaning and spiritual significance to the psilocybin session experience was so striking, correlations were used to examine the relationships between data obtained at screening and the 14-month follow-up data on volunteer's ratings of personal meaning and spiritual significance. Ratings of personal meaning at follow-up were significantly correlated (Pearson's r, df = 34, two-tailed $p < 0.01$) with negative affect on the PANAS-X ($r = -0.51$), raw score on the Quality of Life Inventory ($r = +0.47$), total score on the FaithMaturity Scale ($r = +0.41$) and mean score of the Measure of Actualization Potential questionnaire ($r = +0.44$). There were no significant correlations between any of the outcome measures and the subscales of the NEO PI-R (Neuroticism, Extroversion, Openness, Agreeableness and Conscientiousness) or the total scores on the Mysticism Scale, Spiritual Transcendence Scale or FACIT-Sp-NI.

Relationships between psilocybin session data and the 14-month follow-up data on volunteer ratings of personal meaning and spiritual significance

To further understand the sustained ratings of high personal meaning and spiritual significance, correlations were used to examine the relationships between data obtained on the psilocybin session day and the 14-month follow-up data of volunteer's ratings of personal meaning and spiritual significance. Rating of the experience as personally meaningful correlated significantly (Pearson's r, df = 34, two-tailed $p < 0.01$) with the HRS subscales somaesthesia, affect, perception and cognition ($r = 0.35$, 0.49, 0.42, and 0.46, respectively), the APZ questionnaire subscales OSE-oceanic boundlessness ($r = 0.55$) and VUS-visual restructuralization ($r = 0.54$), total score on Mysticism Scale ($r = 0.65$), and total score on Pahnke-Richards Mystical Experience Questionnaire ($r = 0.65$). Rating of spiritual significance showed a significant correlation with the APZ questionnaire subscales OSE ($r = 0.56$) and VUS ($r = 0.48$), total score on Mysticism Scale ($r = 0.77$), and total score on Pahnke-Richards Mystical Experience Questionnaire ($r = 0.66$). Ratings of personally meaningful and spiritual significance did not significantly correlate with peak monitor ratings during the session of overall drug effect, anxiety or fearfulness, distance from ordinary reality, tearing/crying, joy/intense happiness, or peace/harmony. Figure 3 illustrates the robust correlation between the score on the Mysticism Scale (completed 7 h after psilocybin administration and with reference to the experience during the session) and ratings of the spiritual significance of the experience at the 14-month follow-up. For contrast, the figure also shows the relative lack of relationship between the subject-rated Intensity (of drug effect) HRS scale completed 7 h after psilocybin administration and ratings of the spiritual significance of the experience at the 14-month follow-up.

To further examine the contribution of mystical experience (as measured immediately post-session by the Mysticism Scale) to these follow-up measures, regression analysis controlling for intensity of drug effects was undertaken. Three separate measures of intensity of drug effect were used: peak monitor ratings of overall drug effect; subject-rated intensity as reflected in the Intensity subscale of the HRS questionnaire and subject-rated intensity as assessed by the single item rating 'Intensity' in the HRS questionnaire. For both the rating of personally meaningful and the rating of spiritual significance, the measures of intensity contributed only small non-significant effects. The resulting r-values for scores on Mysticism Scale remained highly significant ($p < 0.0001$): personally meaningful (0.65, 0.61, and 0.61 controlling for the three measures of intensity, respectively); spiritually significant (0.77, 0.78 and 0.74 controlling for the three measures of intensity, respectively).

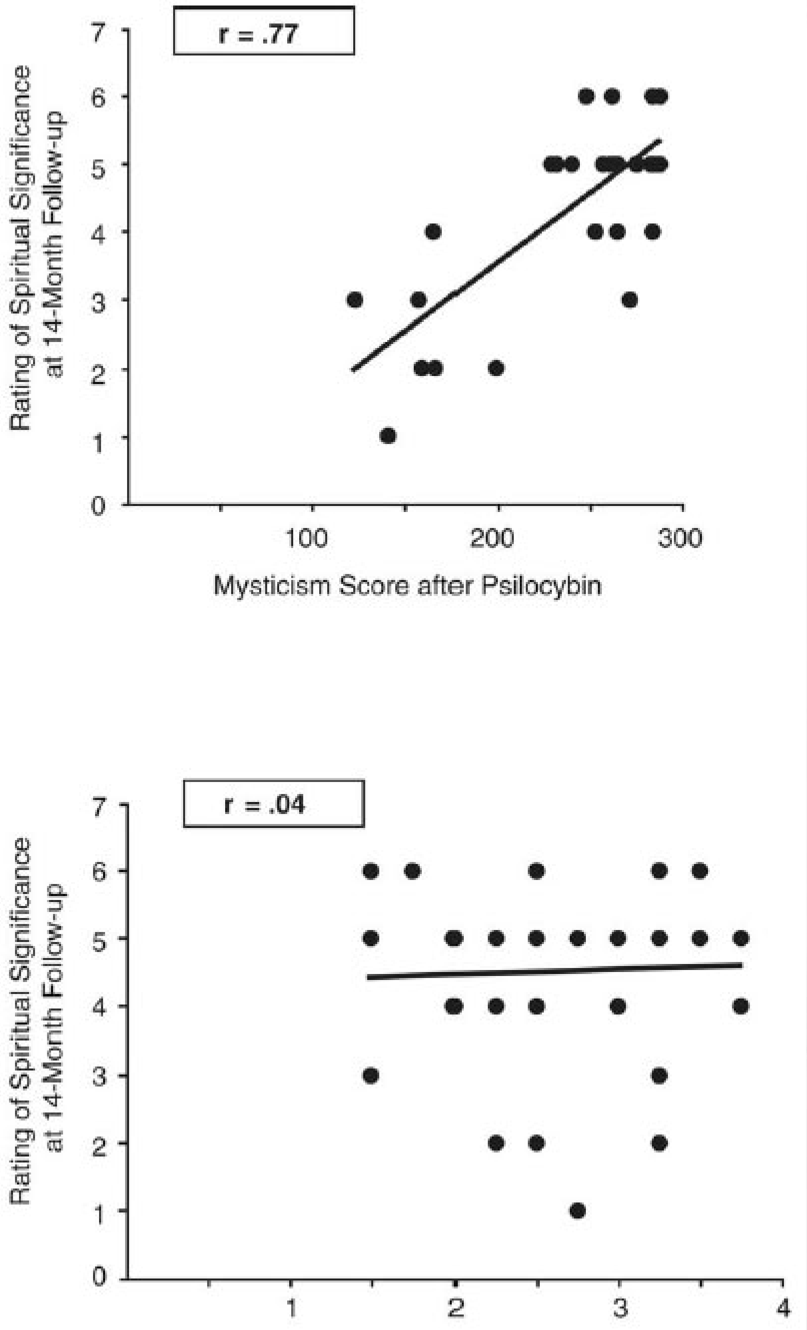

Figure 3. Ratings of the spiritual significance of the psilocybin session experience at the 14-month follow-up as a function of subject ratings complete 7 h after psilocybin administration on the Mysticism Scale (upper panel) and the Intensity subscale of the Hallucinogen Rating Scale (HRS). Data points represent individual subject data (*N* = 36); slope and correlation coefficients are shown.

Verbatim comments at the 14-month follow-up about the nature of the psilocybin-occasioned spiritual experience

Although the patterns of responses on the various subscales of questionnaires provide an empirical representation of the nature of the psilocybin session experiences, unstructured comments from volunteers are helpful to further understand the sustained high ratings of spiritual significance at the 14-month follow-up. Table 3 presents verbatim written comments about the nature of the spiritual experience for all 24 volunteers, who rated the experience at the 14-month follow-up as being among the top five spiritual experiences of their lives. Although not easily summarized, several themes from these unstructured comments include a sense of the unity of all things, a separate 'self' ceasing to exist, and merging and/or an encounter with ultimate reality (or God).

Table 3. Verbatim written comments about the nature of the spiritual experience for all 24 volunteers who rated the experience at the 14-month follow-up as being among the top five (including the single most) spiritual experiences of their lives. These comments were excerpted from the Retrospective Questionnaire that asked open-ended questions about what was most memorable and what was most spiritually significant about the experience.

Volunteer	Verbatim comments
02	The understanding that in the eyes of God - all people...were all equally important and equally loved by God. I have had other transcendent experiences, however, this one was important because it reminded and comforted me that God is truly and unconditionally loving and present.
03	Freedom from every conceivable thing including time, space, relationships, self, etc... It was as if the embodied 'me' experienced ultimate transcendence - even of myself.
04	A non-self self held/suspended in an almost tactile field of light.
05	That in every horrible experience or frightening experience, if you stay with it, enter into it, you will find God. That the horror is in reality only an illusion and God lies beneath it all. It has become a guiding principal in my life.
07	The utter joy and freedom of letting go - without anxiety - without direction - beyond ego self
08	Collapse of ordinary space and time sense. Realization of unity of existence and relativity of ordinary consciousness... I have had glimpses of this before - but this was profound and sustained.
09	The 'knowing' was so powerful and yet personal. Experiencing the Beloved and falling in love.
13	The sense that all is One, that I experienced the essence of the Universe and the knowing that God asks nothing of us except to receive love.
17	I became like a point of awareness able to travel inside myself, others and the outside world. No reference to time or space... The feeling of joy and sadness at the same time - paradoxical.
21	The experience of death, which initially was very uncomfortable, followed by absolute peace and being in the presence of God. It was so awesome to be with God that words can't describe the experience.
23	To cease to 'BE', as I understand it, was not frightening. It was safe and much greater than I have words for or understanding of. Whatever is larger than the state of being is what was holding me.
27	'Surrender' is intensely powerful. To 'let go' and become enveloped in the beauty of - in this case - music - was enormously spiritual.
28	The feeling of no boundaries - where I didn't know where I ended and my surroundings began. Somehow I was able to comprehend what oneness is.
29	The profound grief I experienced as if all of the pain and sadness of the world were passing through me cell by cell tearing apart my being.
32	The breath of God/wind/and my breath are all the same... I really enjoy the deep knowings or truths and laughing about them with 'God'.
36	It opened my third eye - I could see many spiritual beliefs that I hold/held and linked them - a more cohesive and comprehensive spiritual landscape became apparent to me.
37	The experience expanded my conscious awareness permanently. It allows me to let go of negative ideas faster. I accept 'what is' easier.
39	[I experienced] a reality that was clear, beautiful, bright and joyful...In short, this experience opened me up (gave me a tangible vision) of what I think is attainable every day.
40	I felt as if tons of information about 'what is' was being downloaded quickly into my knowing/understanding.
43	The part that continues to stick out for me was 'knowing' and 'seeing' and 'experiencing' with every sense and fiber of my being that all things are connected.
45	When I confronted my shadow and yelled 'What do you want?' and it disappeared in a puff of smoke.
46	The complete and utter loss of self... The sense of unity was awesome... I now truly do believe in God as an ultimate reality.
47	My conversation with God (golden streams of light) assuring me that everything on this plane is perfect; but I do not have the physical body/mind to fully understand.
50	I remember feeling a profound sense of loss of [my family]... I remember after I resolved my fears, the shift then went to joy.

Open-ended clinical interview at the 14-month follow-up

An open-ended clinical interview at the 14-month follow-up provided a clinical context conducive to the spontaneous reporting of study-associated adverse events. There were no reports of persisting perceptual phenomena sometimes attributed to hallucinogen use or of recreational abuse of hallucinogens. Overall, all participants appeared to continue to be well-adjusted, high-functioning and productive members of society.

Comment

The most striking finding from this 14-month follow-up evaluation of the effects of psilocybin and methylphenidate administered to hallucinogen-naïve volunteers is that a large proportion of volunteers rate their 'psilocybin experience'[1] as among the most personally meaningful and spiritually significant of their lives. [[1] Use of the phrase 'psilocybin experience' is not intended to imply that a single type of psilocybin experience exists. Qualitative features of the 'psilocybin experience' may vary widely. The experience is best understood as formed of many factors, including psychological state (i.e. set) and environment (i.e. setting), in addition to the drug.] Fifty-eight per cent and 67% of volunteers, respectively, rated the experience as being among the five most personally meaningful experiences of their lives, and the five most spiritually significant experiences of their lives; 11% and 17%, respectively, indicated that it was the single most meaningful experience, and the single most spiritually significant experience. Furthermore, 64% of the volunteers also indicated that the psilocybin experience increased their sense of well-being or life satisfaction moderately or very much, and no volunteer rated the experience as having decreased well-being or life satisfaction. The magnitude of these effects was undiminished from similar ratings completed 2 months after the psilocybin session and were substantially and significantly greater than ratings completed 2 months after the methylphenidate session. Compared with methylphenidate, attributions to the psilocybin experience also included positive changes in attitudes, mood, altruism, and other behaviour. Although the generalizability of the findings is limited by the study population (hallucinogen-naïve, well-educated, spiritually active, middle-aged adults), it is remarkable that a 8-h laboratory-based intervention could have such large and sustained personally and spiritually significant effects in such a large proportion of volunteers. The findings of sustained reports of positive effects after psilocybin are consistent with a 25-year follow-up study (Doblin, 1991) of seven theological seminary students, who received psilocybin in the context of a religious service (the Good Friday Experiment: Pahnke, 1963, 1967).

One mechanism underlying these effects appears to be that psilocybin occasioned an experience having features similar to spontaneously occurring classical mystical or religious experiences. Of the eight questionnaires measuring personality, affect, quality of life, and spirituality assessed before the study and at follow-up, only the Mysticism Scale-Lifetime showed significant differences (Figure 1). This extensively studied, empirically derived scale is based on the dimensions of mystical experience originally described by William James in 1902 in his classic book 'The Varieties of Religious Experience' (James, 1902) and further elaborated by Stace (1960). Because the version of the scale shown in Figure 1 assesses mystical experience over the entire life-time, it is not possible to attribute the increases observed at both the 2-month and 14-month assessments to the psilocybin experience *per se*. However, the original study (Griffiths, *et al*., 2006) showed that the version of this questionnaire that assessed experience at the end of the session was significantly increased after psilocybin compared with methylphenidate, suggesting that the increases at 2 and 14 months were probably due to the psilocybin experience. Eight dimensions of the mystical experience were also assessed by the Pahnke-Richards Mystical Experience Questionnaire, which documented robust increases on all dimensions after psilocybin (Table 1). Based on *a priori* criteria, almost 60% of the volunteers at the 14-month follow-up continued to fulfil the criteria for having had a 'complete' mystical experience during the psilocybin session. Correlation and regression analyses provided further evidence suggesting a central role of this mystical-type experience in the sustained high ratings of personal meaning and spiritual significance at follow-up, with r-values from regression analyses ranging from 0.74 to 0.78 for the analyses between Mysticism Scale scores immediately after psilocybin sessions and the follow-up ratings of the spiritual significance of the experience. Finally, unstructured written comments in a retrospective questionnaire completed at follow-up asked what was most memorable and spiritually significant about the experience. Responses were suggestive of a sense of the unity (e.g. the unity of all things and merging and/or an encounter with ultimate reality), which is a core aspect of mystical experiences as described by James and Stace, and as assessed by the Mysticism Scale. Thus, the domain(s) of experience assessed by the Mysticism Scale appear to be closely related to later attributions of spiritual significance and personal meaning.

Notably, none of the assessments of personality, affect, quality of life, or spirituality conducted at screening were predictive of (i.e. correlated with) ratings of spiritual significance at follow-up, and only a few of these measures significantly correlated with ratings of personal meaning. Given the large number of correlations conducted and the seeming inconsistency across different types of measures that presumably assess similar domains (e.g. openness as a personality trait was assessed by both the NEO and by the Measurement of Actualization Potential; spirituality as assessed by four separate measures), there do not appear to be any strong predictors of these sustained effects of psilocybin. Future research should explore the replicability of the observed negative correlation of ratings of personal meaning with negative affect and positive correlation with quality of life. Finally, it should be noted that, by design, the volunteer group of this study was relatively homogeneous, with screening measures showing low neuroticism and negative affect and high extroversion, openness, agreeableness and spirituality. It is possible that predictive relationships with such screening measures might emerge in a group showing more variability on such measures.

Although the 14-month follow-up provided no evidence of adverse effects of the psilocybin exposure, it is important not to underestimate the potential risks of hallucinogen exposure. These risks include: (1) panic or fear reactions resulting in dangerous behaviour during the time of drug action; (2) precipitation or exacerbation of enduring psychiatric conditions; (3) long-lasting perceptual disturbances and (4) development of a pattern of abuse of hallucinogens (Abraham, *et al.*, 1996; Halpern and Pope, 1999; Johnson, *et al.*, in press). In the original report of this study (Griffiths, *et al.*, 2006), we reported that 11 of the 36 volunteers experienced a period of significant fear during the psilocybin session, with six having transient ideas of reference/paranoia. These effects did not persist beyond the session. Given the extensive screening, preparation and supportive monitoring in the study protocol, this rate of difficult experience is notable and underscores the possible risk of under-supervised use escalating to panic or dangerous behaviour. Elsewhere, we provide a detailed discussion of the risks of human hallucinogen administration and safety guidelines for minimizing these risks in the context of human research (Johnson, *et al.*, in press).

The high personal meaning and spiritual significance ascribed to the psilocybin-occasioned mystical-type experience prompts consideration of whether such effects could be used to facilitate treatment of some psychiatric and behavioural disorders. Descriptive research suggests that naturally occurring instances of dramatic positive behavioural change are sometimes associated with spontaneously occurring, transformative psychological experiences, frequently of a mystical-type variety (Miller and C'de Baca, 2001; C'de Baca and Wilbourne, 2004; Forcehimes, 2004). Consistent with this, observations in early studies with classical hallucinogens that examined treatment of drug and alcohol dependence (Chwelos, *et al.*, 1959; Kurland, *et al.*, 1971; Savage and McCabe, 1973) and psychological distress associated with advanced cancer (Pahnke, *et al.*, 1969; Richards, *et al.*, 1977) suggested that the occurrence of a mystical-type (i.e. transcendent or peak) experience played a key role in positive therapeutic outcome. Unfortunately, many of the early studies of therapeutic use of hallucinogens used sub-optimal procedures for supporting the experience and/or lacked modern methodological controls now expected of rigorous clinical trials (Mangini, 1998). The present demonstration that mystical experiences having sustained meaning can be occasioned in a high proportion of volunteers suggests that there may be value to re-initiating therapeutic trials with classical hallucinogens.

When administered under supportive conditions, psilocybin occasioned experiences similar to spontaneously occurring mystical experiences that, over a year later, were considered by volunteers to be among the most personally meaningful and spiritually significant experiences of their lives and to have produced positive changes in attitudes, mood, altruism, behaviour and life satisfaction. In addition to possible therapeutic applications, the ability to prospectively produce mystical-type experiences should permit rigorous scientific investigations about their causes and consequences, and may provide novel information about the biological bases of moral and religious behaviour.

Acknowledgements

Conduct of the study was supported by grants from NIDA (R01 DA03889) and the Council on Spiritual Practices. Analysis and write up of the follow-up study was supported by grants from the Council on Spiritual Practices and the Heffter Research Institute. The sponsors were provided the manuscript for comment, but had no role in manuscript approval. Roland Griffiths has been a consultant to or received grants from various pharmaceutical companies on issues about drug abuse liability. The authors thank David Nichols, PhD for synthesizing the psilocybin, Mary Cosimano, MSW for her role as assistant monitor, Brian Richards, PsyD for psychiatric screening, Linda Felch, MA and Paul Nuzzo, MA for statistical analysis, and Dr David Nichols, Dr George Greer andDr Ryan Vandrey for comments on the manuscript.

Abstract

Rationale-This dose-effect study extends previous observations showing that psilocybin can occasion mystical-type experiences having persisting positive effects on attitudes, mood, and behavior.

Objectives-This double-blind study evaluated psilocybin (0, 5, 10, 20, 30 mg/70 kg, p.o.) administered under supportive conditions.

Methods-Participants were 18 adults (17 hallucinogen-naïve). Five 8-hour sessions were conducted individually for each participant at 1-month intervals. Participants were randomized to receive the four active doses in either ascending or descending order (9 participants each). Placebo was scheduled quasi-randomly. During sessions volunteers used eyeshades and were instructed to direct their attention inward. Volunteers completed questionnaires assessing effects immediately after and 1 month after each session, and at 14 months follow-up.

Results-Psilocybin produced acute perceptual and subjective effects including, at 20 and/or 30 mg/70 kg, extreme anxiety/fear (39% of volunteers) and/or mystical-type experience (72% of volunteers). One month after sessions at the two highest doses, volunteers rated the psilocybin experience as having substantial personal and spiritual significance, and attributed to the experience sustained positive changes in attitudes, mood, and behavior, with the ascending dose sequence showing greater positive effects. At 14 months, ratings were undiminished and were consistent with changes rated by community observers. Both the acute and persisting effects of psilocybin were generally a monotonically increasing function of dose, with the lowest dose showing significant effects.

Conclusions-Under supportive conditions, 20 and 30 mg/70 kg psilocybin occasioned mystical-type experiences having persisting positive effects on attitudes, mood and behavior. Implications for therapeutic trials are discussed.

Introduction

Psilocybin, which is the principal psychoactive component of *Psilocybe* and other genera of mushrooms, has likely been used for millennia within some cultures in structured manners for divinatory or religious purposes (Wasson, 1980; Stamets 1996; Metzner 2004; Guzmán 2008). Like other classic hallucinogens (*d*-lysergic acid diethylamide [LSD], mescaline, *N,N*-dimethyltryptamine [DMT]), the effects of psilocybin are primarily mediated at 5-HT_{2A} receptor sites (Glennon et al. 1984; Nichols 2004), and the acute subjective effects include robust changes in perception, cognition, affect, volition, and somesthesia (Isbell 1959; Wolbach et al. 1962; Rosenberg et al. 1964). In early clinical research with psilocybin, the affective character of subjective experiences often varied from positive to negative, and highly valued personal or mystical-type experiences were rare (e.g., Isbell 1959; Malitz et al. 1960; Rinkel et al. 1960; Hollister 1961). Subsequent research that generally used higher psilocybin doses and provided more preparation and interpersonal support reported a higher rate of affectively positive experiences, sometimes of a mystical nature, that were rated as being of personal significance (Leary et al. 1963; Metzner et al. 1965; Pahnke 1969).

Recently, we used rigorous double-blind methods to evaluate the acute (7 hour) and longer-term (2 months and 14 months) psychological effects of a high dose of psilocybin (30 mg/70 kg) relative to an active comparison compound (40 mg/70 kg methylphenidate) in 36 hallucinogen-naïve volunteers (Griffiths et al. 2006, 2008). The study was designed to optimize the potential for positively-valued experiences by providing eight hours of preparation, administering psilocybin in a pleasant, supportive setting, and instructing volunteers to focus explicitly on their subjective or inner experience rather than, for example, perform tasks. The results showed that psilocybin occasioned mystical-type experiences and, sometimes, significant fear. The mystical-type experiences were rated as having substantial and persisting personal meaning and spiritual significance to which volunteers attributed sustained positive changes in attitudes, moods and behavior. The present study was undertaken using similar procedures to characterize the acute and persisting effects of a range of lower doses of psilocybin (0, 5, 10, 20, 30 mg/70 kg). The study was also designed to compare the ascending and descending sequences of drug dose exposure.

Materials and methods

Participants

Participants were recruited from the local community through flyers announcing a study of states of consciousness brought about by psilocybin, a naturally occurring psychoactive substance used sacramentally in some cultures. Two hundred seventy-nine individuals were screened over the telephone and 31 were further screened in person. The 18 study participants (8 males) were medically healthy (as determined by medical history, physical examination, an electrocardiogram, routine medical blood laboratory tests, and urine testing for common drugs of abuse), psychiatrically healthy, and without family histories of psychotic disorders or bipolar I or II disorder (as determined by structured clinical interviews). Individuals with current alcohol or drug dependence (including nicotine) were excluded, as were individuals with a past history within the past 20 years of alcohol or drug dependence (excluding nicotine). Participants were hallucinogen naïve, except for one who reported using psilocybin mushrooms on two occasions more than 20 years previously. Participants had an average age of 46 years (range 29 to 62) and were well-educated; all had at least some college, 94% were college graduates, and 56% had post-graduate degrees. Fifty-six percent were employed full-time, 33% part-time, and 11% were retired. Fifty percent indicated affiliation with a religious or spiritual community, such as a church, synagogue, or meditation group. While not an inclusion criterion, all 18 volunteers indicated at least intermittent participation in religious or spiritual activities such as religious services, prayer, or meditation, with 39% reporting daily activities and an additional 39% reporting at least weekly activities. Volunteers did not receive monetary compensation for participation. Based on interviews, their motivation for participation was curiosity about the effects of psilocybin and the opportunity for extensive self-reflection in the context of the day-long drug sessions and the meetings with the monitors that occurred before and after sessions. The Institutional Review Board of the Johns Hopkins University School of Medicine approved the study, and all volunteers gave their informed consent before participation.

Study design and overview

The study procedures followed recommendations provided for safe conduct of research administering high doses of a classic hallucinogen (Johnson et al. 2008). The study examined psilocybin (0, 5, 10, 20, and 30 mg/70 kg) using a double-blind, between-group, crossover design that involved five 8-hour drug sessions conducted at approximately 1- month intervals, and a 14-month follow-up. Eighteen volunteers were randomly assigned to receive the active psilocybin doses in either an ascending dose sequence or a descending sequence. Although each volunteer received the 0 mg/70 kg condition once, across the 9 volunteers in each of the ascending and descending sequences, the 0 mg/70kg condition occurred twice on sessions 1, 2, 4, and 5, and once on session 3. The purpose of this quasi-random scheduling of placebo was to obscure the dose sequence to the participants and monitors (see Instructions section below). Outcome measures obtained throughout the drug sessions included blood pressure and monitor ratings of participant mood and behavior. At about 7 hours after drug ingestion (when the primary drug effects had subsided), participants completed several questionnaires designed to assess various aspects of hallucinogen experience (described below). Various longitudinal and persisting effects measures were assessed at screening, 1 month after each drug session, and at 14 months after the last session.

Instructions to participants and monitors

Participants and monitors were informed that participants would receive placebo and four different doses (ranging from low to high) of psilocybin in mixed order across sessions. Neither participants nor monitors were informed that the active psilocybin doses would be tested in an ascending or descending sequence. The only exception to this was that two of the seven assistant monitors were not blind to the ascending/descending nature of the experimental design, however they were blind to the outcome of randomization.

Drug conditions

Psilocybin doses and placebo (0 mg/70 kg) were prepared in identically-appearing opaque, size 0 gelatin capsules, with lactose as the inactive capsule filler. On each session, a single capsule was administered with 180 ml water.

Meetings with monitor before and after sessions

The primary monitor (usually along with the assistant monitor) met with each participant on four occasions before his or her first session (for 8 hours total), once for about an hour on the day following each of the five sessions, and one more time about 3 weeks after each session. The purpose and content of these meetings are described elsewhere (Griffiths et al. 2006; Johnson et al. 2008). Monitors and assistant monitors were trained by personnel with extensive prior experience monitoring hallucinogen sessions.

Drug Sessions

As described in more detail previously (Griffiths et al. 2006), drug sessions were conducted in an aesthetic living-room-like environment with two monitors present. Participants were instructed to consume a low-fat breakfast before coming to the research unit. A urine sample was taken to verify abstinence from common drugs of abuse (cocaine, benzodiazepines, and opioids including methadone). Although the presence of THC was not tested, none of the volunteers reported recent use of cannabis. For most of the time during the session, participants were encouraged to lie down on the couch, use an eye mask to block external visual distraction, and use headphones through which a music program was played. The same music program was played for all participants in all sessions. Participants were encouraged to focus their attention on their inner experiences throughout the session.

Measures assessed throughout the session

Ten minutes before and 30, 60, 90, 120, 180, 240, 300, and 360 minutes after capsule administration, blood pressure, heart rate, and monitor ratings were obtained.

Blood pressure and heart rate - Blood pressure (systolic and diastolic pressure using oscillometric method with the blood-pressure cuff placed on the arm) and heart rate were monitored using a Non-Invasive Patient Monitor Model 507E (Criticare Systems, Inc., Waukesha, WI).

Monitor Rating Questionnaire - At the same time-points at which the physiological measures were taken, the two session monitors completed the Monitor Rating Questionnaire, which involved rating or scoring several dimensions of the participant's behavior or mood (Table 1). The dimensions that are expressed as peak scores in Table 1 were rated on a 5- point scale from 0 to 4. Dimensions expressed as total duration in Table 1 were rated as the estimated number of minutes since the last rating. Data were the mean of the two monitor ratings at each time-point.

Measures assessed 7 hours after drug administration

At about 7 hours after capsule administration when the major drug effects had subsided, the participant completed three questionnaires developed for assessing the subjective effects of hallucinogen drugs and two questionnaires developed for assessing mystical experience. Participants typically completed these questionnaires in about 40 minutes.

Hallucinogen Rating Scale - This 99 item questionnaire, which was designed to show sensitivity to the hallucinogen *N,N*-dimethyltryptamine (DMT) (Strassman et al. 1994), consists of six subscales assessing various aspects of hallucinogen effects (Intensity, Somaesthesia, Affect, Perception, Cognition, and Volition).

Table 1. Cardiovascular measures and monitor ratings of volunteer behavior and mood assessed throughout the session.*

Measure	Psilocybin Dose (mg/70 kg)				
	0	5	10	20	30
Cardiovascular Measures (peak effects)					
Systolic blood pressure (mm Hg)	132.6 (3.6)	**143.3 (4.3)**^{a}	**145.7 (4.6)**^{a}	**145.7 (4.2)**^{a}	**153.1 (4.2)**^{b}
Diastolic blood pressure (mm Hg)	77.5 (1.9)	**83.4 (2.1)**^{a}	**83.9 (2.0)**^{a}	**84.3 (2.5)**^{a}	**88.8 (2.4)**^{b}
Heart rate (beats per minute)	74.8 (2.5)	78.7 (2.7)^{a}	77.9 (2.0)^{a}	**81.2 (3.0)**$^{a.b}$	**83.0 (2.4)**^{b}
Monitor Ratings (peak effects, max score=4)					
Overall drug effect	0.69 (0.15)	**2.03 (0.13)**^{a}	**2.44 (0.19)**^{b}	**3.06 (0.15)**^{c}	**3.42 (0.15)**^{c}
Sleepiness/sedation	1.11 (0.22)	0.69 (0.18)	0.78 (0.20)	0.58 (0.16)	0.58 (0.14)
Unresponsive to questions	0.17 (0.09)	**0.19 (0.12)**^{a}	**0.44 (0.14)**^{b}	**0.97 (0.30)**^{c}	**1.14 (0.24)**^{d}
Anxiety or Fearfulness	0.28 (0.10)	**0.61 (0.19)**^{a}	**0.75 (0.15)**^{b}	**1.06 (0.22)**^{c}	**1.19 (0.22)**^{d}
Stimulation/arousal	0.53 (0.19)	**1.19 (0.13)**^{a}	**1.64 (0.19)**^{b}	**1.97 (0.20)**$^{b.d}$	**2.17 (0.22)**$^{c.d}$
Distance from ordinary reality	0.75 (0.17)	**1.92 (0.19)**^{a}	**2.36 (0.21)**^{b}	**2.97 (0.17)**^{c}	**3.22 (0.15)**^{c}
Ideas of reference/paranoid thinking	0.03 (0.03)	0.00 (0.00)^{a}	0.08 (0.05)^{a}	0.14 (0.06)^{a}	**0.44 (0.14)**^{b}
Yawning	0.22 (0.10)	0.53 (0.15)^{a}	**0.97 (0.27)**$^{a.b}$	**1.36 (0.37)**$^{b.c}$	**1.81 (0.39)**^{c}
Tearing/crying	0.61 (0.24)	**1.00 (0.29)**^{a}	**1.25 (0.26)**^{b}	**1.50 (0.33)**^{c}	**1.81 (0.24)**^{d}
Nausea	0.00 (0.00)	**0.33 (0.10)**^{a}	**0.42 (0.15)**^{b}	**0.31 (0.13)**^{c}	**0.47 (0.13)**^{d}
Spontaneous motor activity	0.22 (0.09)	0.64 (0.15)^{a}	**0.78 (0.20)**^{a}	**1.14 (0.32)**$^{a.c}$	**1.47 (0.35)**$^{b.c}$
Restless/fidgety	0.17 (0.07)	**0.44 (0.18)**^{a}	**0.58 (0.12)**^{b}	**0.89 (0.19)**^{c}	**0.81 (0.17)**^{d}
Joy/Intense happiness	0.64 (0.19)	1.19 (0.22)^{a}	**1.42 (0.27)**$^{a.b}$	**1.81 (0.33)**$^{b.c}$	**2.14 (0.31)**^{c}
Peace/harmony	0.78 (0.19)	**1.39 (0.22)**^{a}	**1.64 (0.22)**$^{a.b}$	**2.11 (0.30)**^{b}	**2.03 (0.27)**^{b}
Monitor Ratings (total duration in minutes, max score=360)					
Talking with monitor	85.94 (7.32)	85.42 (6.90)	83.06 (8.08)	83.75 (10.29)	85.03 (11.32)
Physical contact with monitor †	21.64 (7.26)	**35.61 (9.33)**^{a}	**45.00 (12.05)**^{b}	**69.94 (21.31)**^{c}	**86.00 (21.15)**^{d}
Sleep	13.72 (6.80)	3.83 (3.31)	2.67 (1.99)	3.42 (2.13)	0.61 (0.44)
Strong anxiety	0.33 (0.34)	0.61 (0.63)	1.14 (0.69)	1.81 (0.80)	11.11 (6.75)

*Data are means with 1 SEM shown in parentheses (*N*=18); within a row, bold font indicates significant difference from 0 mg/70 kg; for active doses, values not sharing a common letter are significantly different (Fisher's LSD $p<0.05$)

APZ - The APZ is a 72 item yes/no questionnaire designed to assess altered states of consciousness, including those produced by hallucinogens (Dittrich 1998). The three major scales on the APZ are the OSE (oceanic boundlessness; a state common to classic mystical experiences including feelings of unity and transcendence of time and space), the AIA (dread of ego dissolution; dysphoric feelings), and the VUS (visionary restructuralization; includes items on visual pseudo-hallucinations, illusions, and synesthesias). Data on each scale were expressed as a proportion of the maximum possible score.

Addiction Research Center Inventory (ARCI) - The ARCI was developed to differentiate subjective effects among several classes of psychoactive drugs including the hallucinogens (Haertzen 1966). The short form of the ARCI consists of 49 true/false questions and contains five major scales: lysergic acid diethylamide (LSD), a hallucinogen-sensitive scale that is often interpreted as providing a measure of dysphoric changes; pentobarbital, chlorpromazine, alcohol group (PCAG), a sedative sensitive scale; benzedrine group (BG) and amphetamine (A) scales, amphetamine-sensitive scales; and morphine-benzedrine group (MBG), often interpreted as a measure of euphoria (Martin et al. 1971; Jasinski 1977). Participants were instructed to answer the questions on the ARCI with reference to the effects they experienced since they received the capsule that morning.

States of Consciousness Questionnaire - This 100 item questionnaire is rated on a 6-point scale [0=none; not at all; 1=so slight cannot decide; 2=slight; 3=moderate; 4=strong (equivalent in degree to any previous strong experience or expectation of this description); 5=extreme (more than ever before in my life and stronger than 4)]. Forty-three items on this questionnaire comprised the current version of the Pahnke-Richards mystical experience items, which was shown sensitive to psilocybin (Electronic Supplementary Table 1 in Griffiths et al. 2006). An earlier version of this scale was also previously shown sensitive to psilocybin and other hallucinogens (Pahnke 1963; Turek et al. 1974; Richards et al. 1977). The 43 items provide scale scores for each of seven domains of mystical experiences: internal unity (pure awareness; a merging with ultimate reality); external unity (unity of all things; all things are alive; all is one); sense of sacredness (reverence; sacred); noetic quality (claim of an encounter with ultimate reality; more real than everyday reality); transcendence of time and space, deeply-felt positive mood (joy, peace, love); paradoxicality and ineffability (claim of difficulty in describing the experience in words). Data on each domain scale were expressed as a percentage of the maximum possible score. As in previous studies (Pahnke 1969; Griffiths et al. 2006), criteria for designating a volunteer as having had a "complete" mystical experience were that scores on each of the following six scales had to be at least 60%: unity (either internal or external, whichever was greater), sense of sacredness, noetic quality, transcendence of time and space; positive mood; and ineffability. A mean total score was calculated as a mean of all items from the preceding six scales. The remaining 57 items in the States of Consciousness Questionnaire served as distracter items.

Mysticism Scale (Experience-specific) - This 32-item questionnaire, which assesses primary mystical experiences, has been extensively studied and shows cross-cultural reliability (Hood et al. 2001, 2009) and has previously been shown sensitive to psilocybin (Griffiths et al. 2006). A total score and three empirically-derived factors are measured: Interpretation (corresponding to three mystical dimensions: noetic quality, sacredness, and deeply felt positive mood); Introvertive Mysticism (corresponding to the mystical dimensions of internal unity, transcendence of time and space, and ineffability); Extrovertive Mysticism (corresponding to the dimension of the unity of all things/all things are alive). Items were rated on a 9-point scale (Griffiths et al. 2006). For this experience-specific version of the questionnaire used 7 hours after drug administration, participants were instructed to complete the questionnaire with reference to their experiences since they received the capsule that morning.

Persisting effects assessed one month after sessions

At 3 to 4 weeks after each session, and before any additional session, participants returned to the research facility and completed a series of questionnaires to assess possible changes in various standardized measures of personality, mood, and spirituality (not included in this report) as well as possible persisting changes in attitudes, mood, behavior, and spirituality. Participants typically completed these questionnaires in about 75 minutes.

Persisting Effects Questionnaire - This 143-item questionnaire sought information about changes in attitudes, moods, behavior, and spiritual experience that, on the basis of prior research (Pahnke 1969; Doblin 1991, Griffiths et al. 2006), would be sensitive to the effects of psilocybin a month after the session. One hundred forty of the items were rated on a 6-point scale (0=none, not at all; 1=so slight cannot decide; 2=slight; 3=moderate; 4=strong; 5=extreme, more than ever before in your life and stronger than 4). Within the questionnaire, the items were labeled in six categories: Attitudes about life (13 positive and 13 negative items); Attitudes about self (11 positive and 11 negative items); Mood Changes (9 positive and 9 negative items); Relationships (9 positive and 9 negative items); Behavioral changes (1 positive and 1 negative item); Spirituality (22 positive and 21 negative items). The positive and negative items were intermixed within each category. For purposes of scoring the resulting 12 scales (positive and negative scales for each of 6 categories) scores were expressed as the percentage of the maximum possible score. The version of the questionnaire used (available from the authors upon request) was an expanded version of that described by Griffiths et al. 2006. Scale scores on the original and the expanded version were highly correlated (.958-.997) on scales showing reasonable variability. Scales measuring negative effects did not have enough responses and therefore did not have enough variability for these calculations to be meaningful.

The questionnaire included three additional questions (see Griffiths et al. 2006 for more specific wording):
1) How personally meaningful was the experience? (rated from 1-8, with 1=no more than routine, everyday experiences; 7=among the 5 most meaningful experiences of my life; and 8=the single most meaningful experience of my life).
2) Indicate the degree to which the experience was spiritually significant to you? (rated from 1 to 6, with

1=not at all; 5=among the 5 most spiritually significant experiences of my life; 6=the single most spiritually significant experience of my life).
3) Do you believe that the experience and your contemplation of that experience have led to change in your current sense of personal well-being or life satisfaction? (rated from +3=Increased very much; 0=No change; -3=Decreased very much).

Retrospective persisting effects assessed at 14-month follow-up

At 14 months after the last session, participants completed a Retrospective Questionnaire and an open-ended clinical interview reflecting on study experiences and current life situation. For purposes of completing the Retrospective Questionnaire, volunteers were reminded that over the 5 sessions they had received 4 different doses of psilocybin. They were then informed on which two sessions they had received the two highest doses of psilocybin, although they were not informed which of the two was the highest dose. One hundred forty-three items comprised the previously described Persisting Effects Questionnaire. For these items, volunteers were asked to rate any current persisting effects that they attribute to the experiences during either or both the two highest dose sessions.

Volunteers were also asked to provide written descriptions about the session experiences, including how their behavior changed in response to the experiences. Forty-three items on this questionnaire were the previously described mystical experience items from the States of Consciousness Questionnaire, which were completed twice - looking back separately on each of the two sessions associated with the two highest doses. In four final questions, participants were asked, of all five sessions, which session was associated with the strongest effect, which was most personally meaningful, which was most spiritually significant, and which would they chose to repeat if they had the opportunity to do so.

Longitudinal measures assessed at baseline, after session 5, and at 14-month follow-up

More than a dozen longitudinal measures were assessed at screening or shortly after enrollment, after sessions, and at the 14-month follow-up. The results from most of these measures will be combined with results from a previous study (Griffiths et al. 2006) and reported separately. Three measures are reported here.

Mysticism Scale (Lifetime) - Participants were instructed to complete this previously described questionnaire with reference to their lifetime experience.

Death Transcendence Scale - The 26-item Death Transcendence Scale (Hood and Morris, 1983; VandeCreek, 1999) was administered because a potentially important clinical application of psilocybin is in treatment of individuals who are anxious or depressed in response to terminal illness (Grob et al. 2011). Items were rated on a 9-point scale and five subscales were scored: Mysticism, Religious, Nature, Creative, and Biosocial.

Community Observer Ratings of Changes in Participants' Behavior and Attitudes - This previously described measure was shown sensitive to psilocybin 2 months after a high dose session (Griffiths et. al., 2006). After acceptance into the study, each participant designated as raters three adults who were expected to have continuing contact with the participant (e.g. family members, friends, or colleagues at work). Ratings were conducted via a structured telephone interview approximately 1 week after the participant had been accepted into the study, 3 to 4 weeks after the last session, and as part of the 14-month follow-up. The interviewer provided no information to the rater about the participant. The structured interview consisted of asking the rater to rate the volunteer's behavior and attitudes using a 10 point scale (from 1=not at all, to 10=extremely) on eleven items: inner peace; patience; good-natured humor/playfulness; mental flexibility; optimism; anxiety; interpersonal perceptiveness and caring; negative expression of anger; compassion/social concern; expression of positive emotions (e.g. joy, love, appreciation); and self-confidence. On the first rating occasion, which occurred soon after acceptance into the study, raters were instructed to base their ratings on observations of and conversations with the participant over the past 3 months. On subsequent assessments, raters were told their previous ratings and were instructed to rate the participant based on interactions over the last several weeks. Data from each interview with each rater were calculated as a total score, with anxiety and anger scored negatively. Changes in each participant's behavior and attitudes after drug sessions were expressed as a mean change score (i.e. difference score) from the baseline rating across the raters. Rating completion rate was 96%; seven ratings were missed due to a failure to return calls or to the rater not having contact with the volunteer over the rating period.

Post-study monitor ratings of enduring effects in participants

At the conclusion of the study, the primary and assistant monitor for each volunteer were asked to assess any enduring changes in the volunteer's attitudes and behaviors that the monitor believed resulted directly or indirectly from the psilocybin session experiences in the study. Three ratings were done on a 7-point scale (-3=decreased very much; 0=No change; +3=increased very much): 1. Change in volunteer's sense of personal well-being or life satisfaction; 2. Change in quality of volunteer's social relationships (e.g. spouse, family, friends and acquaintances); and 3. Change in the volunteer's sense of spirituality, broadly construed. Score for each volunteer was the mean of the primary and assistant guide ratings for each question.

Data Analyses

Cardiovascular and Monitor Ratings assessed throughout the session - Two sets of analyses were conducted. For the time-course data, Planned Comparisons were conducted comparing the effect of each of the active psilocybin doses with 0 mg/70 kg at each time-point. For the second set of analyses, for each participant, peak scores during the time-course were defined as the maximum value from pre-capsule to 6 hr post-capsule, and temporal measures (e.g. minutes talking or sleeping) were summed across the 8 post-capsule time-points. A repeated measures regression model with AR(1) covariance structure was used with Dose (0, 5, 10, 20, 30 mg/70 kg), Time (10 min before and 0.5, 1, 1.5, 2, 3, 4, 5, and 6 hr after capsule administration), Dose Sequence (ascending vs. descending), and interactions among these as the effects in the model. Fisher's LSD post-hoc tests were used to compare the drug conditions. Two of the seven assistant guides were not blind to the ascending/descending nature of the experimental design, so the analysis described above was repeated excluding ratings from these two monitors. Because there were no differences in the statistical significance of Sequence or Sequence interactions and only minor other differences occurred, the data presented are from all monitor ratings.

Measures assessed 7 hours after drug administration and measures assessed one month after sessions - For the hallucinogen-sensitive questionnaires and the mystical experience questionnaires assessed 7 hours after sessions and for the Persisting Effects Questionnaire assessed one month after sessions, a repeated measures regression was used with Dose (0, 5, 10, 20, 30 mg/70 kg) and Dose Sequence (ascending vs. descending) and their interaction as effects in the model. Fisher's LSD post-hoc tests were used to compare the drug conditions. For analysis of dichotomous responses across the five drug conditions for measures shown in Table 5 (Persisting Effects Questionnaire), Cochran's Q, a non-parametric, binary repeated measures test, was conducted with a factor of Dose (0, 5, 10, 20, 30 mg/70 kg). Planned comparisons for these data were conducted using Wald chi square tests to compare active doses to 0 mg/70 kg.

Retrospective persisting effects assessed at 14 month follow-up - For analysis of the eight scales from the mystical experience items of the States of Consciousness Questionnaire, a repeated measures regression was used with Condition (7 hours after 0 mg/ 70 kg; 7 hours after 30 mg/70 kg; and 14 month retrospective for 30 mg/70 kg), Dose Sequence, and their interaction as effects in the model. Fisher's LSD post-hoc tests were used to compare the conditions. For analysis of dichotomous responses across three sets of conditions (1 month after 0 mg/70 kg; combined data for 1 month follow-ups after both the 20 and 30 mg/70 kg dose sessions; 14 month follow-up data for retrospective rating for either or both the 20 and/or 30 mg/70 kg dose sessions), Cochran's Q was conducted with a factor of Condition (the three conditions described above). Planned comparisons were conducted using Wald chi square tests to compare the three conditions.

Longitudinal measures assessed at screening, after session 5, and at 14-month follow-up - For analysis of the measures of mystical experience, of death transcendence, and of community observer ratings of changes in participants' behavior and attitudes assessed at screening, 1 month after session 5, and at 14-

month follow-up, a repeated measures regression was used with Time (screening, after session 5, and 14-month follow-up) and Dose Sequence and their interaction as effects in the model. Planned comparisons were used to compare screening values with the two post-drug time points. For all statistical analysis, results were considered significant at $p < .05$.

Results

Integrity of blinding procedures

At the conclusion of the study, the primary and assistant guides completed a questionnaire that asked about their understanding of the experimental design. None of the three primary guides or the five assistant guides who were blind the ascending or descending nature of the doses sequences guessed or reported awareness of this aspect of the study procedures.

Cardiovascular measures and monitor ratings assessed throughout the session

Psilocybin produced significant and orderly dose- and time-related effects on cardiovascular measures and monitor ratings assessed throughout the session. At the two highest doses (20 and 30 mg/70kg), onset of significant effects generally occurred at the 30- or 60-minute assessment, with effects usually peaking from 90 to 180 minutes and decreasing toward predrug levels over the remainder of the session (see Figure 1 for illustrative measures). Table 1 shows the mean effects at each dose for these measures. For measures sensitive to psilocybin, effects were generally a monotonically increasing function of dose. For most measures, the 5 mg/70 kg dose was significantly greater than placebo and the 20 and/or 30 mg/70 kg dose(s) were significantly greater than the lower active doses. There were no significant Sequence or Dose x Sequence interactions. The blood pressures of the four volunteers who had the highest pressures 60 minutes or longer after the 30 mg/70 kg psilocybin were: 187/84, 166/64, 182/88, and 178/95 mmHg. These pressures were considered high enough to warrant further repeated blood pressure assessment, however they were not judged to be of sufficient magnitude to necessitate pharmacological treatment.

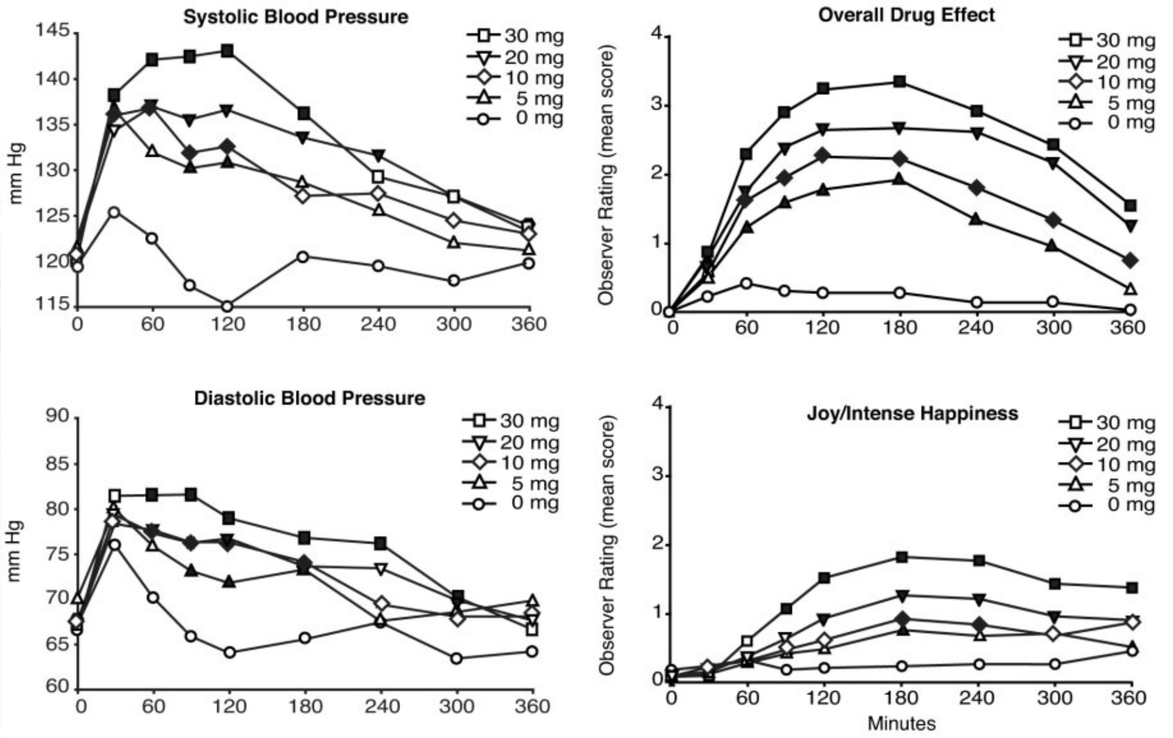

Fig. 1. Within session time-course of psilocybin. Systolic and diastolic blood pressure and monitor ratings of overall drug effect, and joy/intense happiness as a function of time since capsule ingestion (time 0 = before drug administration). Data points are means; filled data points indicate a significant difference from 0 mg/70 kg at the indicated time point (Planned Comparisons).

Drug effect and mysticism measures assessed 7 hours after drug administration

Subjective effects questionnaires - The three questionnaires developed for sensitivity to the subjective effects of hallucinogens showed orderly dose-related increases (Table 2). All six scales of the Hallucinogen Rating Scale, all three scales on the APZ Questionnaire, and the A and LSD scales of the ARCI showed significant and monotonically increasing effects as a function of dose, with significant effects on most measures at even the lowest dose of 5 mg/70 kg. These effects, which are typical of hallucinogens, include perceptual changes (e.g. visual pseudo-hallucinations, illusions, and/or synesthesias), labile moods (e.g. feelings of transcendence, grief, joy, and/or anxiety), and cognitive changes (e.g. sense of meaning, insight, and/or ideas of reference). There were no significant Sequence or Sequence x Dose interactions.

Table 2. Volunteer ratings on three subjective effects questionnaires completed 7 hours after drug administration.*

Questionnaire and Subscale Description	Psilocybin Dose (mg/70kg)				
	0	5	10	20	30
Hallucinogen Rating Scale

* Data are mean scores with 1 SEM shown in parentheses (*N*=18); within a row, bold font indicates significant difference from 0 mg/70 kg; for active doses, values not sharing a common letter are significantly different (Fisher's LSD $p<0.05$)

Measures of mystical experience - Also at 7 hours after capsule administration, volunteers completed two questionnaires designed to assess mystical experience (Table 3). The total score and all three empirically-derived factors of the Mysticism Scale and all seven scales on States of Consciousness Questionnaire showed significant and monotonically increasing effects as a function of dose, with significant effects at the 5 mg/70 kg dose. The proportion of volunteers who met *a priori* criteria for having had a "complete" mystical-type experience on the States of Consciousness Questionnaire was also an increasing function of dose: 0, 5.6, 11.1, 44.4, and 55.6% at 0, 5, 10, 20, and 30 mg/70kg, respectively. Overall, 72.2% of volunteers had "complete" mystical experiences at either or both the 20 and 30 mg/70 kg session. Only the Mysticism Scale showed an effect of Sequence or a Dose x Sequence interaction. This effect was largely due to differences in response to placebo. Examination of the position of the placebo condition within the sequence suggested this result was spurious.

Table 3. Volunteer ratings on two mystical experience questionnaires completed 7 hours after drug administration and at 14 month follow-up.*

Questionnaire and Subscale Description	7 Hours after Drug Administration					14 Month Follow-up (30 mg/70 kg)[‡]
	Psilocybin Dose (mg/70 kg)					
	0[†]	5[†]	10[†]	20[†]	30[†]

* Data are mean scores with 1 SEM shown in parentheses (N=18); data for the States of Consciousness Questionnaire are expressed as a percentage of the maximum possible score.

[†] Data in these columns show rating data 7 hours after the indicated dose of psilocybin; within the same row for these columns, bold font indicates significant difference from 0 mg/70 kg; for active doses, values not sharing a common letter are significantly different (Fisher's LSD p<0.05).

[‡] For the States of Consciousness Questionnaire, data in this column show ratings of the 30 mg/70 kg session experience at the 14 month follow-up; each value in this column was significantly greater than the value at 0 mg/70 kg after 7 hours (as indicated by bold font) but was not different from the value at 30 mg/kg 1 month (Fisher's LSD p<0.05); 14 month follow-up data were not obtained for the experience-specific version of the Mysticism Scale (indicated by N/A), although data were obtained for the Lifetime version (see text).

Psilocybin-Induced Fear/Anxiety or Delusions

Although volunteers were carefully screened and psychologically prepared, and close interpersonal support was provided during sessions, on questionnaires completed at the end of the session, 39% of participants (7 of 18) had extreme ratings of fear, fear of insanity or feeling trapped at some time during the session. Such episodes occurred in 6 of 7 of these participants after the 30 mg/70 kg dose and in 1 of 7 after the 20 mg/70 kg dose. Monitor ratings of peak anxiety/fear during the session showed dose-rated increases, with each dose producing a significantly higher rating than the lower doses (Table 1). After 30 mg/70 kg, monitor ratings of anxiety/fear across the session showed varying time-courses of onset and duration, with peak effects of anxiety/fear being rated as early as 60 minutes in some participants, but as late as 180 or 240 minutes in others (see Figure 2 for illustrative data). Forty-four percent of participants (8 of 18) reported delusions or paranoid thinking sometime during the session; such episodes occurred in 7 of 8 of these participants after the 30 mg/70 kg dose and in 1 of 7 after 20 mg/70 kg dose. Examples of delusions included the belief that a child or loved one had died during the time of the session, or that the session monitors were malevolently manipulating the participant. Three of 8 volunteers who had such episodes were those who also rated extreme fear or fear of insanity. Inspection of the data indicated that delusions and extreme ratings of fear/anxiety were not differentially affected by dose sequence.

These psychological struggles did not affect the overall rate of having "complete" mystical experiences as rated by volunteers at the end of the session day. Five of seven (71%) of participants reporting extreme fear, insanity or feeling trapped provided data consistent with "complete" mystical experiences, and 4 of 8 (50%) of participants who had delusions or paranoid thinking provided data consistent with "complete" mystical experiences. These rates of "complete" mystical experience are generally similar to the rate for the group as a whole (56%). Although psychological struggles did not affect the overall rate of "complete" mystical experience, it should be noted that neither of the two volunteers who had the most sustained anxiety during the 30 mg/70 kg session (Figure 2, square and circle symbols) had a "complete" mystical experience. In addition to not affecting rate of mystical experience, inspection of the data indicated no consistent relationship between psychological struggle and subsequent ratings of the session as having personal meaning and spiritual significance. No volunteer rated the overall experience as having decreased her or his sense of well-being or life satisfaction.

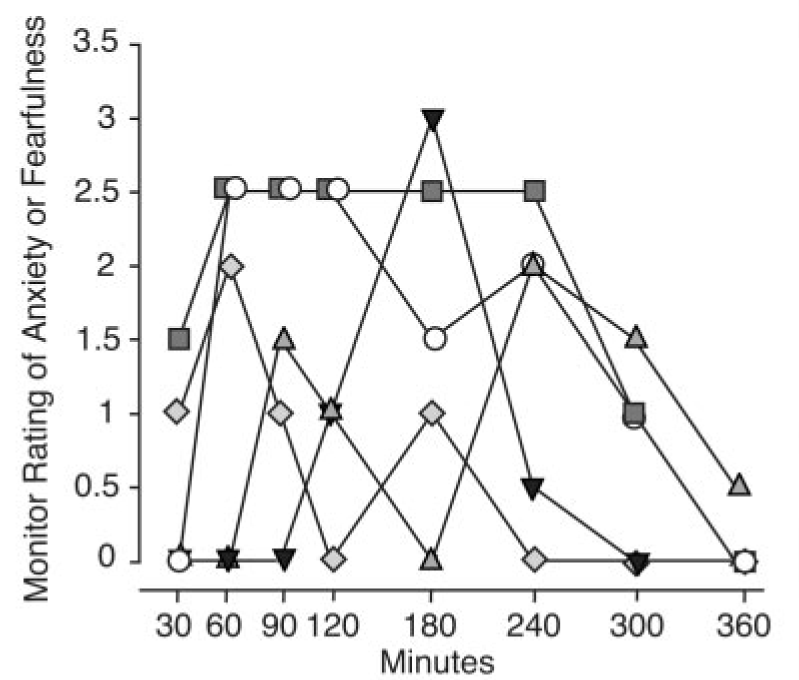

Fig. 2. Time-course of monitor ratings of anxiety or fearfulness after 30 mg/70 kg in the five volunteers whose mean ratings were 2.0 or higher at one or more time point. Data points are mean ratings of the two session monitors. Different symbols represent different volunteers. The figure illustrates the unpredictable time-course of anxiety or fear across the session.

The volunteer who had the most sustained anxiety during the 30 mg/70 kg dose session (Fig. 2, square symbols) provides an interesting case example. Likely as a consequence of the sustained psychological struggle during the session, this volunteer also had the lowest mystical experience rating immediately after the session of all 18 volunteers studied. Immediately after the session, this volunteer, who for decades had held reincarnation as part of her worldview, reported that it was the worst experience of her life and that she would rather spend three lifetimes on a mountaintop meditating than repeat what she had just experienced during the session. Although she considered dropping out of the study after this first session and she remained hesitant to receive psilocybin again, over the next several weeks she increasingly felt that she had learned something useful from the experience. At 1 month, she rated the experience as having slight spiritual significance and as having slightly increased her sense of well-being or life satisfaction. Because she remained curious about the effects of psilocybin, she decided to continue to participate in the study. She received 20 mg/70 kg psilocybin on the second session. In contrast to her first session, her post-session ratings fulfilled criteria for a "complete" mystical experience and, at 1 month, she retrospectively rated this experience as the single most personally meaningful and spiritually significant of her life.

Persisting effects assessed one month after sessions

Persisting Effects Questionnaire - As shown in Table 4, psilocybin produced significant and generally monotonically increasing effects as a function of dose in positive ratings of attitudes about life, attitudes about self, mood, social effects, and behavior. Negative ratings of these same dimensions were very low and did not differ across the doses except for negative attitudes about self that showed small but significant increases at the two lowest doses. Table 4 also shows that ratings of the personal meaningfulness and spiritual significance of the experience, and ratings of well-being or life satisfaction were significant and a monotonic increasing function of dose. Of the persisting effects measures shown in Table 4, all six of the positive subscales (attitudes about life, attitudes about self, mood, altruism, behavior, and spirituality) and one of the three questions (sense of well-being/life satisfaction) showed significant Dose x Dose Sequence interactions. Inspection of these data showed that this effect was primarily due to the ascending dose sequence producing relatively larger effects at the 20 and 30 mg/70 kg doses and relatively smaller effects at lower doses compared to the descending dose sequence. Figure 3 shows this effect for two representative measures: persisting effects on well-being/life satisfaction and on positive mood.

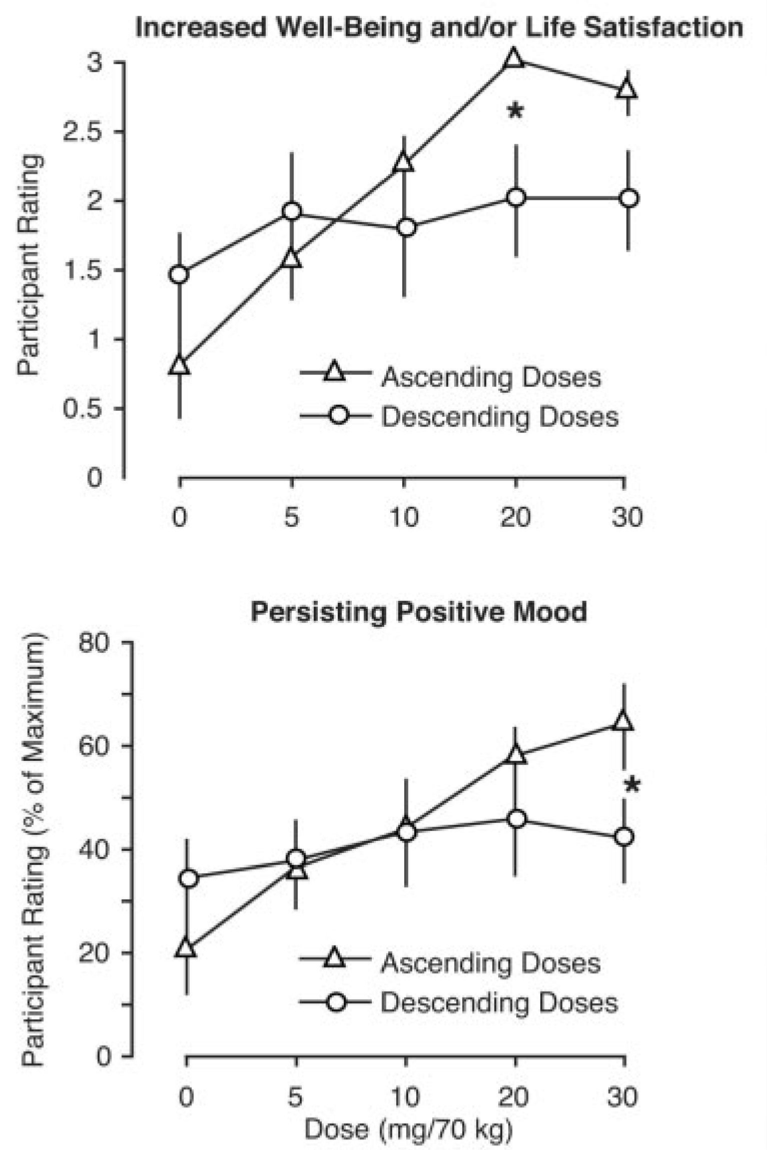

Fig. 3. Effects of dose sequence on ratings of persisting effects of well-being/life satisfaction and positive mood completed one month after sessions. Data points are means and brackets show 1 SEM for participants in the ascending dose sequence (triangles) and the descending dose sequence (circles). Dose x Dose Sequence interactions were significant. Asterisks indicate a significant difference between the ascending and descending dose sequence at the indicated dose (Fisher's LSD post hoc).

Table 5 shows the percentages of volunteers who endorsed specific outcomes on four items on the Persisting Effects Questionnaire. Endorsement increased as a function of dose. Notably, 61% of volunteers considered the psilocybin experience during either or both the 20 and 30 mg/70 kg sessions to have been the single most spiritually significant of their lives, with 83% rating it in their top 5. Consistent with this, 94%, and 89% of volunteers, respectively, indicated that the experiences on those same sessions increased their well-being or life satisfaction and positively changed their behavior at least moderately. Of the 90 total sessions, none were rated as having decreased well-being or life satisfaction.

Retrospective persisting effects assessed at 14-month follow-up

The right-most columns of Tables 3, 4 and 5 show that the retrospective ratings at the 14-month follow-up on the States of Consciousness Questionnaire mystical experience items and on the Persisting Effects Questionnaire were undiminished from ratings obtained 1 month after sessions. No participant rated that their behavior was affected negatively or that their well-being/life satisfaction was decreased as a result of the psilocybin experiences on the two highest dose sessions. The analysis of the States of Consciousness Questionnaire mystical experience items showed significant Condition x Dose Sequence Interactions on Internal Unity, Mood, and Total score. Inspection of these data showed that the ascending dose sequence was associated with relatively larger effects at 30 mg/70 kg both post-session and at 14-month follow-up.

When asked at 14 months which of the five sessions seemed strongest, 83% and 17% of volunteers indicated the session associated with 30 and 20 mg/70 kg, respectively; most personally meaningful (44%, 44%, and 11% at 30, 20, and 10 mg/70 kg, respectively); most spiritually significant (56%, 33%, and 11% at 30, 20, and 10 mg/70 kg, respectively); and which session they would want to repeat if they had an opportunity to do so (67%, 28% and 6% at 30, 20 and 10 mg/70 kg, respectively).

Table 4. Volunteer ratings of persisting effects 1 month and 14 months after sessions.[*]

Questionnaire and Subscale Description	1 Month after Sessions					14 Month Follow-up (20 or 30 mg/70 kg)[‡]
	Psilocybin Dose (mg/70 kg)					
	0[†]	5[†]	10[†]	20[†]	30[†]	
Persisting Effects Questionnaire						
Positive attitudes about life	33.3 (6.6)	**45.9 (5.6)**^{a}	**50.3 (6.6)**^{a}	**62.2 (5.6)**^{b}	**65.9 (5.9)**^{b}	68.8 (4.8)
Negative attitudes about life	0.6 (0.4)	0.8 (0.5)	1.4 (0.6)	0.8 (0.4)	0.6 (0.4)	3.2 (1.3)
Positive attitudes about self	31.9 (6.1)	**44.4 (5.4)**^{a}	**46.5 (6.2)**^{a,c}	**54.2 (5.5)**^{b,c}	**58.9 (6.0)**^{b}	61.1 (5.4)

Negative behavior changes	0.0 (0.0)	2.2 (2.3)	2.2 (2.3)	0.0 (0.0)	0.0 (0.0)	0.0 (0.0)
Increased spirituality	31.1 (6.2)	**42.3 (6.7)**^{a}	**48.2 (7.0)**^{a,b}	**57.9 (6.2)**^{b}	**58.3 (5.8)**^{b}	71.6 (6.3)
Decreased spirituality	0.4 (0.3)	0.2 (0.2)	0.6 (0.3)	0.6 (0.4)	0.8 (0.4)	1.1 (0.6)
How personally meaningful was the experience? (max score=8)	3.33 (0.40)	**5.06 (0.36)**^{a}	**5.56 (0.43)**^{a}	**6.67 (0.31)**^{b}	**6.67 (0.34)**^{b}	7.22 (0.22)
How spiritually significant was the experience? (max score=6)	2.72 (0.35)	3.28 (0.27)^{a}	**3.94 (0.32)**^{a,c}	**4.67 (0.31)**^{b,c}	**4.94 (0.33)**^{b}	5.28 (0.23)
Did the experience change your sense of well-being or life satisfaction? (max score=3)	1.11 (0.23)	**1.72 (0.25)**^{a}	**2.0 (0.25)**^{a,c}	**2.5 (0.22)**^{b}	**2.39 (0.21)**^{b,c}	2.39 (0.22)

[*] Data are mean scores with 1 SEM shown in parentheses (*N*=18); data on attitudes, mood, altruistic/social effects, and behavior changes are expressed as percentage of maximum possible score; data for the final three questions are raw scores.

[†] Data in these columns show rating data 1 month after the indicated dose of psilocybin; within the same row for these columns, bold font indicates significant difference from 0 mg/70 kg; for active doses (Fisher's LSD $p<0.05$), values not sharing a common letter are significantly different (Fisher's LSD $p<0.05$)

[‡] Data in this column show ratings at the 14 month follow-up; ratings were completed with respect to experiences during either or both the 20 and 30 mg/70 kg dose sessions (see Methods); no statistical comparison was conducted

Consistent with the flattened dose-effect curve for persisting effects shown in Fig. 3, most volunteers in the ascending dose sequence rated the highest dose session (30 mg/70 kg) as the most personally meaningful (67%) and spiritually significant (78%) of the five sessions; in contrast, a smaller proportion of volunteers in the descending sequence rated the highest dose session as most personally meaningful (22%) and spiritually significant (22%). The mean ± 1 SEM dose of the sessions that were rated as being the most personally meaningful were 25.6 ± 2.6 and 21.1 ± 1.8 in the ascending and descending dose sequence, respectively

(N.S.); similar ratings of spiritual significance were 27.8 ± 2.6 and 21.1 ± 1.5 respectively (*p*<.05, *t*-test).

Table 5. Percentage of volunteers endorsing specific outcomes on four persisting effects items 1 month and 14 months after sessions.*

Questionnaire Items	1 Month after Sessions						14 Month Follow-up (20 or 30 mg/70 kg)**
	Psilocybin Dose (mg/70 kg)						
	0†	5†	10†	20†	30†	20 lub 30‡	
How personally meaningful was the experience?							
Single most meaningful experience of life	0.0	0.0	5.6	16.7	**33.3**	**44.4**	**38.9**
Top 5 most meaningful, including single most	0.0	11.1	**33.3**	**77.8**	**61.1**	**77.8**	**94.4**
How spiritually significant was the experience?							
Single most spiritually significant experience of life	0.0	0.0	5.6	**27.8**	**44.4**	**61.1**	**44.4**
Top 5 most spiritually significant, including single most	11.1	11.1	**44.4**	**66.7**	**77.8**	**83.3**	**94.4**
Did the experience change your sense of well-being or life satisfaction?							
Increased well-being/life satisfaction (very much)	5.6	**27.8**	**38.9**	**72.2**	**55.6**	**77.8**	**61.1**
Increased well-being/life satisfaction (moderately or very much)	38.9	55.6	**72.2**	**83.3**	**88.9**	**94.4**	**83.3**
Your behavior changed in ways you would consider positive since the experience.							
Positive behavioral change (strong or extreme)	22.2	16.7	**50.0**	38.9	**55.6**	**55.6**	**44.4**
Positive behavioral change (moderate, strong or extreme)	33.3	50.0	61.1	61.1	**88.9**	**88.9**	**88.9**

* Data in table show the percentage of volunteers endorsing the specific outcome.

† Data in these columns are the percentage of volunteers endorsing the specific outcome 1 month after the indicated dose of psilocybin; within the same row for these columns, bold font indicates significant difference in pair-wise comparisons to 0 mg/70 kg (Cochran's Q showed *p*<.001 for all variables; planned comparisons performed with Wald test; see Methods for details).

‡ Data in this column are the percentage of volunteers endorsing the specific outcome 1 month after either or both the 20 and 30 mg/70 dose sessions; bold font indicates significant difference in pair-wise comparisons to 0 mg/70 kg (Cochran's Q showed *p*<.05 for all variables; planned comparisons performed with Wald test; see Methods for details).

** Data in this column are the percentage of volunteers at 14 month follow-up endorsing the specific outcome with respect to experiences during either or both the 20 and 30 mg/70 kg dose sessions (see Methods); each value in this column was significantly greater than the value at 0 mg/70 kg (as indicated by bold font) but was not significantly different from the value at 20 or 30 mg/kg at 1 month (Cochran's Q showed *p*<.05 for all variables; planned comparisons performed with Wald test; see Methods for details).

Also at the 14-month follow-up, participants provided written descriptions, based on their memories of their two highest dose sessions, of how they thought their behavior changed in response to those experiences. As summarized in Table 6, only 2 volunteers indicated no positive change in their behavior. The domains of change most frequently cited were better social relationships with family and others, increased physical and psychological self-care, and increased spiritual practice.

Longitudinal measures assessed at baseline, after session 5, and at 14-month follow-up

Longitudinal measures of mystical experience, of death transcendence, and of community observer ratings of changes in participants' behavior and attitudes showed effects generally consistent with the previously described persisting effects. After session 5 and at 14-month follow-up, the total score (as well as each of the three subscales) of the Mysticism Scale (Lifetime) was significantly higher than at screening (217.9 ± 10.8, 264.1 ± 6.8, and 260.4 ± 7.6, means and SEMs for total scores at screening, post-session 5, and 14-month follow-up, respectively)(Planned comparisons, *p*<.0001). The Religious subscale of the Death Transcendence Scale, which assesses a sense of continuity after death, showed similar increases (28.72 ± 1.57, 31.00 ±, 0.99, and 31.28 ± 1.07, means and SEMs for screening, post-session 5, and 14-month follow-up, respectively)(Planned comparisons, *p*<.05). The other subscales were not significant. For the community observer ratings of participants' behavior and attitudes, change scores from those taken about 1 week after study enrollment (means ± SEMs) were significant both after session 5 (8.85 ± 1.64) and at the 14-month follow-up (5.36 ± 1.68)(Planned comparisons, *p*<.001).

Table 6. Self-reported behavior change. Verbatim written comments about the nature of behavioral changes volunteers attributed to either or both the two highest dose psilocybin session experiences in the Retrospective Questionnaire completed at the 14-month follow-up.

Volunteer	Verbatim Comments
201	Virtually eliminated all religious practices; much more spiritual now. Accepting of my parents and have a more open and honest dialogue with them. Less judgmental and more open hearted. Taken a more active role in pursuing what I want for myself.
202	I have an increased commitment to spiritual practices; I think my heart is more open to all interactions with other people; more aware of choices, take time to pause and choose, more breaks; better boundaries at work and personal relationships.
205	I have a stronger desire for devotion, have increased yoga practice and prayer. I have better interaction with close friends and family and with acquaintances and strangers... I feel more certain of my career as an author. I need less food to make me full. My alcohol use has diminished dramatically... I consider myself to be better [at self-care] now than before the study...
206	Feel closer to family and friends. Incorporating Ayurvedic theory into diet and self care. [Also changed her meditation and yoga practice]
207	More regular meditation; more mindful with family; more generous with strangers; started new yoga practice; more relaxation of pace of change.
210	I feel that I relate better in my marriage. There is more empathy - a greater understanding of people and understanding their difficulties and less judgment. Less judging of myself too.
211	I take more time in nature, with art. I feel closer to children and parents. I am more comfortable with friends and acquaintances. I am more committed to my career. I eat better and have taken up dance...
213	Increased time for meditation. I think I'm even warmer towards people and more accepting. I now believe I have something important to tell people about how the universe works. I am slowing learning to give myself a break.
214	[This participant endorsed no specific behavior change, although did report an increased sense of spirituality]
215	I try to judge less and forgive more. I no longer worry about money.
217	More frequent and enjoyable meditation; more desire to connect with loving energy and have loving energy flow through me to others; less willingness to allow manipulative or abusive treatment to happen without my confronting it.
218	A greater integration of the pieces of my life; more spirit less religion; less fear of being wrong.
219	More fulfilling meditation; more appreciation of and openness to others [and] my own emotional reactions.
222	Less concerned with the appearance of "spirituality", while realizing more that everything is sacred. I feel more accommodating and forgiving toward both friends and strangers, and less anxious to label them or convert them to my viewpoint. I am learning to recognize and release old definitions of myself.
223	During my sessions, much was shown to me about letting go of attachment around my son. More and more, sensuality and passion and gratitude continue to unfold and deepen within me.
226	The energy experience stoked my curiosity about the spiritual awakening stimulus of kundalini [spiritual energy] and has opened a new path for me!
228	[This participant endorsed no specific behavior change, although did report a deeper appreciation of positive emotional experience and empathy]
230	I am more aware and accepting [of everyone]. I have a thousand ideas to write about and am making time and space in my life to accommodate them.

Post-study monitor ratings of enduring effects in participants

The post-study monitor ratings of enduring effects in participants were consistent with the participant self-ratings and the community observer ratings of changes in participants' behavior and attitudes. Mean ± SEM of monitor ratings of the volunteers' personal wellbeing/ life satisfaction, quality of social relationships, and sense of spirituality were all in the positive direction (2.33 ± 0.14, 1.64 ± 0.14, and 2.41 ± 0.15, respectively).

Open-ended clinical interview at the 14-month follow-up

An open-ended clinical interview at the 14-month follow-up was conducive to the spontaneous reporting of possible persisting adverse events. There were no reports of bothersome or clinically significant persisting perception phenomena sometimes attributed to hallucinogen use. Likewise, there were no reports of any non-study use of hallucinogens since study enrollment. All 18 volunteers appeared to continue to be psychiatrically healthy, high-functioning, productive members of society.

Discussion

The present study demonstrated orderly dose-related increases in the effects of psilocybin on volunteer and observer ratings of drug effect and on the cardiovascular measures of blood pressure and heart rate. Notably, even the 5 mg/70 kg (71 μg/kg) dose of psilocybin produced significant subjective, physiological, and observer-rated effects. This is the lowest dose of psilocybin demonstrated to produce significant effects. A previous study showed dose-related effects of psilocybin at doses of 45, 115, 215, and 315 μg/kg, however did not show statistically significant effects at the lowest dose (Hasler et al. 2004). Consistent with previous findings, the present study showed orderly time-related observer-rated and cardiovascular effects during the session, with significant effects at the highest doses generally occurring at 30-60 minutes, peaking at 90-180 minutes, and decreasing toward pre-drug levels over the remainder of the session (Griffiths et al. 2006).

The present study extends previous observations showing that psilocybin can occasion mystical-type experiences having sustained personal and spiritual significance (Pahnke 1963; Doblin 1991; Griffiths et al. 2006, 2008). Two volunteer-rated measures of mystical-type experience completed at the end of the session days showed dose-related increases, with 72% of volunteers fulfilling criteria for having had a "complete" mystical experience at either or both of the two highest dose sessions. Retrospective ratings of mystical experience and spiritual significance did not diminish in time. One month after either or both the two highest dose sessions, 83% of participants rated the experience as the single most or among the 5 most spiritually significant experiences of their life. At the 14-month follow-up, this number was even higher (94%). Likewise, at 14 months, retrospective ratings of mystical experience at the highest dose were generally slightly higher than at the 1-month rating time. Finally, longitudinal measures of lifetime mystical experience and of death transcendence (Religious subscale) were significantly increased over screening levels at both one month and 14 months after the final session. The significant increase in the Religious subscale of the Death Transcendence Scale is notable in this group of healthy volunteers because questions in this subscale assess a sense of continuity after death (e.g. Death is a transition to something even greater than this life; Death is never just an ending, but a part of a process). This effect may be relevant to the proposed palliative effects of psilocybin and similar hallucinogens in treating existential anxiety in terminal illness (Kast 1967; Richards et al. 1972; Grob et al. 2011).

The present study also extends previous observations indicating that psilocybin can occasion persisting positive changes in attitudes, mood, life satisfaction, behavior, and altruism/social effects (Griffiths et al. 2006, 2008). All of these domains showed dose-related increases one month after sessions, with effects at the highest doses sustained at the 14-month follow-up. One month after sessions at either or both the two highest dose sessions, 94% of volunteers endorsed that the experience increased their sense of well-being or life satisfaction moderately or very much, and 89% rated moderate or higher changes in positive behavior. At the 14-month follow-up, these ratings remained high. The types of behavior change most frequently cited by volunteers were better social relationships with family and others, increased physical and psychological self-care, and increased spiritual practice (Table 6). Ratings by community observers before and after the study as well as ratings by study monitors after the study were consistent with the persisting positive changes in behavior and attitudes claimed by the volunteers. The persisting positive changes, particularly in attitudes, mood, and life satisfaction, occasioned by psilocybin appear similar in kind and breadth to the enduring changes reported in case studies of individuals who have had spontaneously-occurring mystical- or insightful-types of experiences (Miller and C' de Baca, 2001).

A novel aspect of the present study was that it compared effects in volunteers who received the four active psilocybin doses in either an ascending or a descending dose sequence. Although the acute measures of psilocybin effects were not affected by the dose sequence, volunteer-rated positive changes in attitudes and behavior assessed 1 month after each session showed Dose x Dose Sequence interactions reflecting relatively larger effects at the highest psilocybin doses than the lower doses in the ascending dose sequence compared to the descending sequence (Figure 2). Analogous differences occurred at the 14-month follow-up assessment on the mystical experience items of the States of Consciousness Questionnaire and on retrospective ratings of the personal meaning and spiritual significance associated with various session doses. Overall, these findings suggest that the ascending dose sequence is somewhat more likely than the descending sequence to produce long-lasting positive changes in attitudes, behavior, and remembered mystical-type experiences. Thus it appears that having experience with lower doses facilitates the likelihood of having sustained positive effects after a high dose of psilocybin. The biological or psychological mechanisms underlying this effect are unknown. This finding suggesting an advantage of an ascending dose sequence may have clinical application in the design of therapeutic studies of psilocybin (Griffiths and Grob, 2010; Grob et al. 2011). It is noteworthy, however, that this finding is contrary to some older recommendations of psychotherapists who administered classic hallucinogens. Specifically, in one report (Blewett and Chwelos, 1959) psychotherapists inferred from their clinical experience that a single high-dose overwhelming experience was more therapeutic than an approach that began with a small doses and gradually increased the dose over successive experiences.

Also of relevance to the design of future research trials with psilocybin, the present study provides information about the relative likelihood of different doses of psilocybin to occasion acute adverse subjective effects as well as mystical-type effects having persisting positive effects. The acute anxiety/fear-producing effects of psilocybin, as assessed by monitor and volunteer ratings, increased with increasing doses. Thirty-nine percent of volunteers reported extreme fear, fear of insanity, or feeling trapped sometime during the session (0 at placebo or the two lower doses, 1 at 20 mg/70 kg, and 6 at 30 mg/70 kg). Furthermore, 44% of volunteers reported delusions or paranoid thinking sometime during the session (0 at placebo and the two lower doses, 1 at 20 mg/70 kg, and 7 at 30 mg/70 kg). In the present study, such negative effects were well managed with reassurance in the highly supportive setting. Interestingly, these psychological struggles did not generally affect rates of having "complete" mystical experiences, possibly because the negative feelings were most often of short duration. However, under conditions in which volunteers are less well screened and psychologically prepared, or sessions are not as well supervised, there could be a possibility that extreme anxiety and/or delusion could be prolonged and result in dangerous behavior. Under such conditions, administration of doses higher than about 20 mg/70 would be inadvisable. The unpredictable time-course across the session of anxiety or fear (Fig.2) underscores the importance that session monitors remain vigilant throughout the session.

Furthermore, the unpredictable time-course of anxiety, in combination with the finding that even experienced session monitors cannot rate with high reliability whether or not psilocybin has been administered (Griffiths *et al.*, 2006), suggests the potential risk of the recommendation by some psychotherapists that a "booster" dose of a classic hallucinogen should be administered relatively shortly after the initial dose if the effects are less than expected (Blewett and Chwelos, 1959; Stolaroff 1997).

In a therapeutic or other research trial, the possibility of such potentially adverse effects should be considered in relationship to the potential persisting positive effects. The proportion of volunteers having "complete" mystical-type experiences, which likely mediate persisting positive effects (Richards et al. 1977; Griffiths et al. 2008), as well as the persisting positive effects (Table 4 and 5) were generally an increasing function of dose, with the percentage change from 20 to 30 mg/70 kg varying widely (-23% to a +99%), with a mean of +17%. However, endorsement of having had a "complete" mystical experience, or of having had the single most spiritually significant experience of his/her life increased 25% and 60%, respectively from 20 to 30 mg/70 kg. Likewise, endorsement of moderate to extreme positive behavioral change, which may be the most relevant outcome measure in some therapeutic trials, increased 45% from 20 to 30 mg/70 kg. Thus, in addition to considering the extent of screening and support provided to volunteers, the decision to administer psilocybin doses higher than about 20 mg/70 kg should be made on the basis of the type of outcome desired.

The present study provided no evidence of adverse effects of high dose psilocybin exposure other than the episodes of psychological struggle during some portion of the time of psilocybin action. This should not be interpreted to suggest that casual use of high dose psilocybin is safe. It is important to recognize that the present study was conducted in carefully screened volunteers who received ample preparation before sessions, were closely monitored during sessions, and had some continuing contact with study staff after sessions (see Johnson *et al.*, 2008 for detailed safety guidelines for minimizing risks of high dose hallucinogen exposure in human research). The reported potential risks of hallucinogen exposure include: (1) panic or fear reactions resulting in dangerous behavior during the time of drug action; (2) precipitation or exacerbation of enduring psychiatric conditions; (3) long-lasting perceptual disturbances and (4) development of an abusive pattern of hallucinogen use (Abraham, *et al.*, 1996; Halpern and Pope, 1999; Johnson, *et al.*, 2008).

The generalizability of the results of the present study is limited by the study population, a group of hallucinogen-naïve, well-educated, psychologically stable, mostly middle-aged adults, most of whom reported at least weekly participation in religious or spiritual activity. It would be particularly interesting to determine whether volunteers who identified as atheist or agnostic would be as likely to have mystical-type experiences and whether they would ascribe spiritual significance to such experiences. It would also be interesting to compare hallucinogen-naïve volunteers with past users to provide information about whether the novelty of effects in naïve volunteers contributes to the high persisting ratings of personal meaning and spiritual significances.

Overall, the present study shows that psilocybin can dose-dependently occasion mystical-type experiences having persisting positive effects on attitudes, mood, and behavior. The observations that episodes of extreme fear, feeling trapped, or delusions occur at the highest dose in almost 40% of volunteers, that anxiety and fear have an unpredictable time-course across the session, and that an ascending sequence of dose exposure may be associated with long-lasting positive changes have implications for the design of therapeutic trials with psilocybin. Considering the rarity of spontaneous mystical experiences in the general population, the finding that more than 70% of volunteers in the current study had "complete" mystical experiences suggests that most people have the capacity for such experiences under appropriate conditions and, therefore, such experiences are biologically normal.

Acknowledgments

Conduct of this research was supported by grants from the Council on Spiritual Practices, the Heffter Research Institute, and the Betsy Gordon Foundation. Effort for Roland Griffiths, Ph.D. in writing this paper was partially provided by NIH grant RO1DA03889. We thank David Nichols, Ph.D. for synthesizing the psilocybin, Mary Cosimano, M.S.W. for her role as a primary session monitor, Maggie Klinedinst for data management, and Linda Felch M.A. and Paul Nuzzo, M.A. for statistical analyses. We also thank Larry Carter, Ph.D., Ryan Lanier, Ph.D., Benjamin McKay, Chad Ressig, Ph.D., and Ryan Vandrey, Ph.D. for serving as assistant session monitors. The study was conducted in compliance with United States laws.

Abstract

Rationale Although psilocybin has been used for centuries for religious purposes, little is known scientifically about its acute and persisting effects.

Objectives This double-blind study evaluated the acute and longer-term psychological effects of a high dose of psilocybin relative to a comparison compound administered under comfortable, supportive conditions.

Materials and methods The participants were hallucinogen-naïve adults reporting regular participation in religious or spiritual activities. Two or three sessions were conducted at 2-month intervals. Thirty volunteers received orally administered psilocybin (30 mg/70 kg) and methylphenidate hydrochloride (40 mg/70 kg) in counterbalanced order. To obscure the study design, six additional volunteers received methylphenidate in the first two sessions and unblinded psilocybin in a third session. The 8-h sessions were conducted individually. Volunteers were encouraged to close their eyes and direct their attention inward. Study monitors rated volunteers' behavior during sessions. Volunteers completed questionnaires assessing drug effects and mystical experience immediately after and 2 months after sessions. Community observers rated changes in the volunteer's attitudes and behavior.

Results Psilocybin produced a range of acute perceptual changes, subjective experiences, and labile moods including anxiety. Psilocybin also increased measures of mystical experience. At 2 months, the volunteers rated the psilocybin experience as having substantial personal meaning and spiritual significance and attributed to the experience sustained positive changes in attitudes and behavior consistent with changes rated by community observers.

Conclusions When administered under supportive conditions, psilocybin occasioned experiences similar to spontaneously occurring mystical experiences. The ability to occasion such experiences prospectively will allow rigorous scientific investigations of their causes and consequences.

Keywords Psilocybin, Methylphenidate, Hallucinogen, Entheogen, Mystical, experience, Spiritual, Religion, Anxiety, Humans

Introduction

Psilocybin, a naturally occurring tryptamine alkaloid with actions mediated primarily at serotonin 5-HT$_{2A/C}$ receptor sites, is the principal psychoactive component of a genus of mushrooms (*Psilocybe*) (Presti and Nichols 2004). Psilocybin, in the form of these mushrooms, has been used for centuries, possibly millennia, within some cultures in structured manners for divinatory or religious purposes (Wasson 1980; Stamets 1996; Metzner 2004). The psychological effects of psilocybin, which are similar to other classical serotonergically mediated hallucinogens [lysergic acid diethylamide (LSD), mescaline, and *N*,*N*-dimethyltryptamine (DMT)], include significant alterations in perceptual, cognitive, affective, volitional, and somatesthetic functions, including visual and auditory sensory changes, difficulty in thinking, mood fluctuations, and dissociative phenomena (Isbell 1959; Wolbach *et al*. 1962; Rosenberg *et al*. 1964).

Early clinical research with psilocybin in the 1950s and early 1960s attempted to study the effects of psilocybin without recognition of the powerful influences of set and setting (e.g., Isbell 1959; Hollister 1961; Malitz *et al*. 1960; Rinkel *et al*. 1960). Subsequent research, which included more preparation and interpersonal support during the period of drug action, found fewer adverse psychological effects, such as panic reactions and paranoid episodes, and increased reports of positively valued experiences (Leary *et al*. 1963; Metzner *et al*. 1965; Pahnke 1969). In response to the epidemic of hallucinogen abuse that occurred in the 1960s, clinical research with psilocybin and other hallucinogens largely ceased and has resumed only recently. Notably, Vollenweider and colleagues from Switzerland and Gouzoulis- Mayfrank from Germany have reported a series of studies that have characterized the acute subjective, physiological, and perceptual effects of psilocybin (e.g., Vollenweider *et al*. 1998; Gouzoulis-Mayfrank *et al*. 1999; Hasler *et al*. 2004; Carter *et al*. 2005).

In the present study, we sought to use rigorous double-blind clinical pharmacology methods to evaluate both the acute (7 h) and longer-term (2 months) mood-altering and psychological effects of psilocybin (30 mg/70 kg) relative to an active comparison compound (40 mg/70 kg methylphenidate). The study was conducted with 36 well-educated, hallucinogen-naïve volunteers.

Materials and methods

Participants

The participants were recruited from the local community through flyers announcing a "study of states of consciousness brought about by a naturally occurring psychoactive substance used sacramentally in some cultures." There were 135 individuals screened over the telephone and 54 were further screened in person. The 36 study participants (14 males) were medically and psychiatrically healthy, without histories of hallucinogen use, and without family histories of schizophrenia or other psychotic disorders or bipolar I or II disorder. The participants had an average age of 46 years (range 24 to 64) and were well educated; 97% (35 volunteers) were college graduates and 56% (20 volunteers) had post-graduate degrees. Eighty-three percent (30 volunteers) were employed full time, with the remainder employed part time. Fifty-three percent (19 volunteers) indicated affiliation with a religious or spiritual community, such as a church, synagogue, or meditation group. All 36 volunteers indicated at least intermittent participation in religious or spiritual activities such as religious services, prayer, meditation, church choir, or educational or discussion groups, with 56% (20 volunteers) reporting daily activities and an additional 39% (14 volunteers) reporting at least monthly activities. The volunteers did not receive monetary compensation for participation. Although most volunteers had very busy personal and professional schedules, they were interested in the study and made participation a priority. Based on interviews, their motivation for participation was curiosity about the effects of psilocybin and the opportunity for extensive self-reflection in the context of both the day-long drug sessions and the meetings with the monitors that occurred between sessions. The Institutional Review Board of the Johns Hopkins University School of Medicine approved the study, and all volunteers gave their informed consent before participation.

Study design

The study compared psilocybin (30 mg/70 kg) and methylphenidate hydrochloride (40 mg/70 kg) using a double-blind between-group, crossover design that involved two or three 8-h drug sessions conducted at 2-month intervals. Thirty-six volunteers were randomly assigned to receive either two sessions (N=30) or three sessions (N=6). The group of 30 volunteers were then randomly assigned to receive psilocybin or methylphenidate on the first session (15 per group), with the alternative drug administered on the second session. The other six volunteers received methylphenidate on the first two sessions and unblinded psilocybin on the third session. The purpose of this condition was primarily to obscure the study design to the participants and monitors (see "Expectancy" section), and data from the six participants were not used in the statistical analyses; however, those data were generally consistent with the results described in this report. Outcome measures obtained throughout the drug sessions included blood pressure and monitor ratings of participant mood and behavior. At about 7 h after drug ingestion (when the primary drug effects had subsided), the participants completed several questionnaires designed to assess various aspects of hallucinogen experience (described below). The longitudinal measures assessed before and 2 months after each drug session included measures of psychiatric symptoms, personality measures, quality of life, and lifetime mystical experiences. A 1-year follow-up assessment is still underway.

Drug conditions

Psilocybin and methylphenidate were administered in identically appearing opaque, size 0 gelatin capsules with approximately 180 ml water. The dose of psilocybin (30 mg/70 kg) was selected as a high safe dose based on non-blind (Malitz *et al*. 1960; Metzner *et al*. 1965; Leuner 1981) and blind (Pahnke 1963, 1969) studies conducted with hallucinogen-naïve individuals in the 1950s-1960s. The methylphenidate dose (40 mg/70 kg) was selected for the comparison condition because it is a high, discriminable but safe dose, it has an onset and duration of subjective effects similar to psilocybin, and it produces some subjective effects (e.g., excitability, nervousness, and/or increased positive mood) overlapping with those of psilocybin (Chait 1994; Rush *et al*. 1998; Kollins *et al*. 1998).

Meetings with monitor before and after sessions

The primary monitor met with each participant on four occasions before his or her first session (for 8 h total) and on four occasions (for 4 h total) after each session. A major purpose of the participant-monitor meetings was to develop and maintain rapport and trust, which is believed to minimize the risk of adverse reactions to psilocybin (Metzner *et al*. 1965). During these meetings, the participant's life history and current life circumstances were reviewed. The preparation of participants by the monitors explicitly included the monitor's expectation that the drug session experiences could increase personal awareness and insight, however, avoided even mention of the criteria used to assess mystical experiences. A male clinical psychologist (W.R.) with extensive prior experience monitoring hallucinogen sessions and a female clinically trained social worker (M.C.) served as primary and assistant monitors, respectively, for all study participants.

Drug sessions

The participants were instructed to consume a low-fat breakfast before reporting to the research unit at 0800 hours, about 1 h before drug administration. A urine sample was taken to verify drug-free status, and the participants were encouraged to relax and reflect before drug administration. The 8-h drug sessions were conducted in an aesthetic living-room- like environment designed specifically for the study. Two monitors were present with a single participant throughout the session. For most of the time during the session, the participant was encouraged to lie down on the couch, use an eye mask to block external visual distraction, and use headphones through which a classical music program was played. The same music program was played for all participants in all sessions. The participants were encouraged to focus their attention on their inner experiences throughout the session. If a participant reported significant fear or anxiety, the monitors provided reassurance verbally or physically (e.g., with a supportive touch to the hand or shoulder). The sessions were videotaped and about 25% were reviewed by the first author to verify session procedures.

Expectancy

It is widely believed that expectancy plays a large role in the qualitative effects of hallucinogens (Metzner *et al*. 1965). Some expectancy effects are unavoidable because it would be unethical not to inform both the participants and the session monitors about the range of possible effects with hallucinogens. In addition, it is believed by many that ethical hallucinogen administration requires that sessions be monitored by individuals who are familiar with such altered states of consciousness (Masters and Houston 1966; Roberts 2001; Stolaroff 2001). Thus, the beliefs of the session monitors introduce another source of expectancy. While it was not possible to completely eliminate such expectancy effects, it was possible to significantly reduce such effects by studying participants without personal histories of hallucinogen use, by studying only a single participant at a time, and by using an experimental design and instructional sets that provided the expectation that sessions could involve not only the administration of a wide range of psilocybin doses but also a range of novel drugs, some of which could produce effects that overlap with those produced by psilocybin. Expectancy effects were also reduced because the experimental design was further obscured from both participants and monitors, who were not aware of which or how many participants would have a final unblinded psilocybin session (see "Instructions to participants and monitors").

Instructions to participants and monitors

The participants and monitors were informed that the participants would have either two or three sessions and that, in at least one session, they would receive a moderate or high dose of psilocybin. They were informed that an inactive placebo, a low dose of psilocybin or various doses of 11 other drugs that could produce various effects (dextromethorphan, nicotine, diphenhydramine, caffeine, methylphenidate, amphetamine, codeine, alprazolam, diazepam, triazolam, or secobarbital), could be administered in sessions in which a moderate or high dose of psilocybin was not administered. After data collection 2 months after the second session, the six participants who received methylphenidate on the first and second session were informed that they would have a third session that would involve administration of a moderate or high dose of psilocybin. These six sessions were the only unblinded sessions. To help focus the participants on their experiences during the sessions, they were not asked to guess whether or not they received psilocybin. However, the monitors completed a rating form which recorded their guesses about the contents of capsules approximately 7 h after capsule administration but before the participant completed detailed questionnaires describing his or her experiences. The participants were given no information about these or any other monitor ratings.

Measures assessed throughout the session

Ten minutes before and 30, 60, 90, 120, 180, 240, 300, and 360 min after capsule administration, monitor ratings, blood pressure, and heart rate were obtained.

Blood pressure and heart rate

Blood pressure (systolic, diastolic, and mean arterial pressure using oscillometric method with the blood pressure cuff placed on the arm) and heart rate were monitored using a Non-Invasive Patient Monitor Model 507E (Criticare Systems, Waukesha, WI, USA).

Monitor rating questionnaire

At the same time-points at which the physiological measures were taken, the two session monitors completed the Monitor Rating Questionnaire, which involved rating or scoring 20 dimensions of the participant's behavior or mood (Table 1). The dimensions expressed as peak scores in Table 1 were rated on a five-point scale from 0 to 4. The dimensions expressed as total duration in Table 1 were rated as the estimated number of minutes since the last rating. The data were the mean of the two monitor ratings at each time-point.

Measures assessed 7 h after drug administration

At about 7 h after capsule administration, when the major drug effects had subsided, the participants completed three empirically derived (i.e., via factor analysis) questionnaires assessing subjective drug effects and two questionnaires assessing mystical experience, as described below. The participants typically completed these questionnaires in about 40 min.

Hallucinogen rating scale

This 99-item questionnaire, which was designed to show sensitivity to the hallucinogen *N,N*-dimethyltryptamine (Strassman *et al*. 1994; Riba *et al*. 2001), consists of six subscales assessing various aspects of hallucinogen effects (intensity, somaesthesia, affect, perception, cognition, and volition).

APZ

The APZ is a 72-item yes/no questionnaire designed to assess altered states of consciousness induced by drug (e.g., DMT or psilocybin) or non-drug (e.g., perceptual deprivation, hypnosis, and sensory overload) manipulations (Dittrich 1998). The three major scales on the APZ are the OSE (oceanic boundlessness, a state common to classic mystical experiences including feelings of unity and transcendence of time and space), the AIA (dread of ego dissolution, dysphoric feelings similar to those of some "bad trips" described by hallucinogen users), and the VUS (visionary restructuralization, which includes items on visual pseudo-hallucinations, illusions, and synesthesias). The data on each scale were expressed as a proportion of the maximum possible score.

Addiction research center inventory (ARCI)

The ARCI was developed to differentiate subjective effects among several classes of psychoactive drugs including hallucinogens (Haertzen 1966). The short form of the ARCI consists of 49 true/false questions and contains five major scales: lysergic acid diethylamide (LSD, a hallucinogen-sensitive scale that is often interpreted as providing a measure of dysphoric changes); pentobarbital, chlorpromazine, and alcohol group (PCAG, a sedative sensitive scale); benzedrine group (BG); amphetamine (A) scales (amphetamine-sensitive scales); and morphine-benzedrine group (MBG, often interpreted as a measure of euphoria) (Martin *et al*. 1971; Jasinski 1977). The participants were instructed to answer the questions on the ARCI with reference to the effects they experienced after they received the capsules that morning.

States of consciousness questionnaire

This 100-item questionnaire is rated on a six-point scale [0=none, not at all; 1=so slight, cannot decide; 2=slight; 3=moderate; 4=strong (equivalent in degree to any previous strong experience or expectation of this description); and 5=extreme (more than ever before in my life and stronger than 4)]. Forty-three items on this questionnaire comprised the current version of the Pahnke-Richards Mystical Experience Questionnaire (Pahnke 1969; Richards 1975), which was designed to assess mystical experiences, used as a primary outcome measure in the Good Friday Experiment (Pahnke 1963; Doblin 1991), and has been shown to be sensitive to other hallucinogens (Turek *et al*. 1974; Richards *et al*. 1977). This questionnaire is based on the classic descriptive work on mystical experiences and the psychology of religion by Stace (1960), and it provides scale scores for each of seven domains of mystical experiences: internal unity (pure awareness; a merging with ultimate reality); external unity (unity of all things; all things are alive; all is one); transcendence of time and space; ineffability and paradoxicality (claim of difficulty in describing the experience in words); sense of sacredness (awe); noetic quality (claim of intuitive knowledge of ultimate reality); and deeply felt positive mood (joy, peace, and love). The specific items in each of the scales of the Pahnke-Richards Mystical Experience Questionnaire are available online as Electronic Supplementary Material, Table 1. The data on each scale were expressed as a proportion of the maximum possible score. Based on prior research (Pahnke 1969), the criteria for designating a volunteer as having had a "complete" mystical experience were that the scores on each of the following scales had to be at least 0.6: unity (either internal or external, whichever was greater), transcendence of time and space, ineffability, sense of sacredness, noetic quality, and positive mood. The remaining 57 items in the questionnaire served as distracter items.

Mysticism scale

This 32-item questionnaire was developed to assess primary mystical experiences (Hood *et al*. 2001; Spilka *et al*. 2005). The Mysticism Scale has been extensively studied, demonstrates cross-cultural generalizability, and is well regarded in the field of the psychology of religion (Hood *et al*. 2001; Spilka *et al*. 2005) but has not previously been used to assess changes after a drug experience. A total score and three empirically derived factors are measured: interpretation (corresponding to three mystical dimensions described by Stace (1960): noetic quality, deeply felt positive mood, and sacredness); introvertive mysticism (corresponding to the Stace dimensions of internal unity, transcendence of time and space, and ineffability); and extrovertive mysticism (corresponding to the dimension of the unity of all things/all things are alive). The items were rated on a nine-point scale (−4=this description is extremely not true of my own experience or experiences; 0=I cannot decide; and +4=this description is extremely true of my own experience or experiences). For the version of the questionnaire used 7 h after drug administration, the participants were instructed to complete the questionnaire with reference to their experiences after they received the capsules that morning.

Measures assessed 2 months post-session

At 7 to 8 weeks after each session and before any additional session, the participants returned to the research facility and completed a series of questionnaires to assess possible persisting changes in attitudes, mood, or behavior as well as possible changes in standardized measures of personality, mood, and spirituality. The participants typically completed these questionnaires in about 75 min.

At about this same time, community observer ratings of participants' attitudes and behavior were obtained by telephone. The outcome measures at this time-point are described below.

Persisting Effects Questionnaire

This 89-item questionnaire sought information about changes in attitudes, moods, behavior, and spiritual experience that, on the basis of prior research (Pahnke 1963, 1969; Doblin 1991; Richards *et al*. 1977), would possibly be sensitive to the effects of psilocybin 2 months after the session. Eighty-six of the items were rated on a six-point scale (0=none, not at all; 1=so slight, cannot decide; 2=slight; 3=moderate; 4=strong; and 5=extreme, more than ever before in your life and stronger than 4). Sixty-six of the items were from Pahnke (1963, 1969) and 20 items were new. For purposes of summarizing the results before data analysis, 61 of the 86 items were judged as likely to be unambiguously divided into six categories: positive attitudes about life and/or self, negative attitudes about life and/or self, positive mood changes, negative mood changes, altruistic/positive social effects, and antisocial/negative social effects. Six raters independently sorted the 61 items into the six categories. Three items were excluded because fewer than five of the six raters agreed on the categories. For the remaining 58 items, at least five of the six raters agreed with the assignment of each item to each category, suggesting the appropriateness of the category descriptors. The category descriptors and the number of items associated with each category were: positive attitudes about life and/or self (17 items), negative attitudes about life and/or self (17 items), positive mood changes (four items), negative mood changes (four items), altruistic/positive social effects (eight items), and antisocial/negative social effects (eight items). Two additional categories were comprised of one item each: positive behavior change and negative behavior change. For scoring purposes, the eight category scores based on a total of 60 items were expressed as the percentage of the maximum possible score. The items in each of the categories of the Persisting Effects Questionnaire are available online as electronic supplementary material, Table 2. The remaining 23 items in the questionnaire that did not readily fit into the categories predominately reflected aspects of spirituality and mystical experience; these domains were characterized by other outcome measures.

The questionnaire also included these three questions: (1) How personally meaningful was the experience (rated 1= no more than routine, everyday experiences; 2= similar to meaningful experiences that occur on average once or more a week; 3=similar to meaningful experiences that occur on average once a month; 4=similar to meaningful experiences that occur on average once a year; 5=similar to meaningful experiences that occur on average once every 5 years; 6=among the 10 most meaningful experiences of my life; 7=among the 5 most meaningful experiences of my life; and 8=the single most meaningful experience of my life)? (2) Indicate the degree to which the experience was spiritually significant to you (rated 1=not at all, 2=slightly, 3=moderately, 4=very much, 5=among the 5 most spiritually significant experiences of my life, and 6=the single most spiritually significant experience of my life). (3) Do you believe that the experience and your contemplation of that experience have led to change in your current sense of personal well-being or life satisfaction (rated +3=increased very much, +2=increased moderately, +1=increased slightly, 0=no change, −1=decreased slightly, −2=decreased moderately, and −3=decreased very much)? This questionnaire was developed after the initiation of the study and was completed by all 24 of the 30 participants who thereafter received psilocybin and methylphenidate in counterbalanced order in the first two sessions (12 participants in each of the two drug orders).

Mysticism Scale-Lifetime

The Lifetime version of this previously described questionnaire instructed the participants to answer questions with reference to their total life experiences. This questionnaire was completed at screening and at 2 months after each session.

Spiritual Transcendence Scale

This 24-item questionnaire assesses a construct that reflects an individual's effort to create a broad sense of personal meaning in his or her life and has been shown to demonstrate cross-cultural generality (Piedmont 1999, 2005, 2006; Piedmont and Leach 2002). A total score and three empirically derived factors are scored: prayer fulfillment, universality, and connectedness. This questionnaire was completed at screening and at 2 months after each session.

NEO Personality Inventory (NEO PI-R)

This 241-item questionnaire, which was completed on a computer, permits the assessment of five major personality factors: neuroticism, extraversion, openness, agreeableness, and conscientiousness (Costa and McCrae 1992). This questionnaire was completed at screening and at 2 months after each session.

PANAS-X (Positive and Negative Affect Schedule Expanded Form)

This 60-item questionnaire permits the assessment of two broad general factors (positive affect and negative affect) accounting for most of the variance in self-rated affect (Watson and Clark 1994, 1997). The version of the questionnaire used instructed the participants to answer questions based on how they feel on the average. This questionnaire was completed at screening and at 2 months after each session.

Community observer ratings of changes in participants' behavior and attitudes

After acceptance into the study, each participant designated three adults who were expected to have continuing contact with the participant (e.g., family members, friends, or coworkers/colleagues at work) such that they would be likely to observe changes in the participants' behavior and attitudes that might occur during the study. Ratings by the designated individuals were conducted via a structured telephone interview approximately 1 week after the participant had been accepted into the study and 7 to 8 weeks after each of the drug sessions. The interviewer provided no information to the community volunteer about the participant. Furthermore, most of the interviews (60%) were conducted by a research assistant who had never met the participant and had no knowledge about the participant's experiences during drug sessions. The structured interview consisted of asking the rater to rate the volunteer's behavior and attitudes using a ten-point scale (from 1=not at all to 10=extremely) on 11 dimensions that were identified from prior research (Pahnke 1963; Richards *et al*. 1977; Doblin 1991) as possibly sensitive to the effects of psilocybin. The rated dimensions were: inner peace, patience, good-natured humor/playfulness, mental flexibility, optimism, anxiety, interpersonal perceptiveness and caring, negative expression of anger, compassion/social concern, expression of positive emotions (e.g., joy, love, appreciation), and self-confidence. On the first rating occasion, which occurred soon after acceptance into the study, the raters were instructed to base their ratings on observations of and conversations with the participant over the past 3 months. On subsequent ratings, which occurred 7 to 8 weeks after each session, the raters were told their previous ratings and were instructed to rate the participant based on interactions over the last several weeks. The data from each interview with each rater were calculated as a total score, with anxiety and anger scored negatively. The changes in participants' behavior and attitudes after drug sessions were expressed as a mean change score from the preceding rating across the raters.

A failure to interview all three of the raters after one of the drug sessions resulted in elimination of 4 of the 30 participants who received psilocybin and methylphenidate in counterbalanced order on the first two sessions. Of the 52 rating occasions in the 26 participants, the majority (83%) involved interviews with all three raters on each rating occasion, with all of the remaining interviews conducted with two raters.

Data analyses

The data were statistically analyzed for the 30 participants who received psilocybin and methylphenidate in counterbalanced order on the first two sessions.

Physiological and monitor rating questionnaire assessed throughout the session

Two sets of analyses were conducted. For the first, a two-factor analysis of variance was used with drug (psilocybin and methylphenidate) and time (10 min before and 0.5, 1, 1.5, 2, 3, 4, 5, and 6 h after capsule administration) as within-subject factors. The mean square error term for the drug × time interaction was then used to conduct Tukey's honestly significant differences (HSD) post hoc tests comparing psilocybin and methylphenidate at each post-drug-administration time point. For the second set of analyses, the peak scores during the time-course were defined as the maximum value from 0.5 to 6 h after capsule administration, and temporally based measures (i.e., minutes sleeping and minutes speaking) were summed across the eight post-capsule time-points. Paired *t* tests were used to compare psilocybin and methylphenidate conditions.

Measures assessed 7 h after drug administration (data analysis)

Paired *t* tests were used to compare psilocybin and methylphenidate conditions on the three measures of subjective drug effect (Hallucinogen Rating Scale, APZ, and Addiction Research Center Inventory) and the two questionnaires assessing mystical experience (States of Consciousness Questionnaire and Mysticism Scale).

Measures assessed 2 months post-session (data analysis)

Paired *t* tests were used to compare psilocybin and methylphenidate conditions for the 24 participants who completed the Persisting Effects Questionnaire and the 26 participants for whom complete data were obtained for the community observer ratings of changes in participants' attitudes and behavior.

The remaining four questionnaires completed 2 months post-session (NEO, PANAS-X, Mysticism Scale-Lifetime, and Spiritual Transcendence Scale) provide general measures of personality, affect, and spirituality that could result in carry-over effects from post-session 1 to post-session 2. Accordingly, these data were analyzed using the following planned comparisons: (1) comparison (*t* test) of data obtained at screening for the group of participants that received psilocybin in session 1 (N=15) with that for the group that received methylphenidate in session 1 (N=15), (2) comparison (*t* test) of post-session 1 data for the group of participants that received psilocybin in session 1 (N=15) with the group that received methylphenidate in session 1 (N=15), and (3) comparison (paired *t* test) of data post-session 1 with data post-session 2 for the group of participants that received methylphenidate on session 1 and psilocybin on session 2 (N=15).

Results

Integrity of blinding procedures

The integrity of the blinding procedures was assessed by having the monitors complete a questionnaire after each session on which they guessed the capsule content and a questionnaire at the end of the study on which they provided their guesses about the study design. Overall, 23% of sessions were misclassified (methylphenidate identified as psilocybin or psilocybin identified as something other than psilocybin) by one or both of the monitors. The primary and most experienced monitor had an overall misclassification rate of 17%. Most misclassification errors involved rating a methylphenidate session as psilocybin. It is interesting to note that even the primary monitor, however, sometimes rated the psilocybin condition, which was a high dose, as being something other than psilocybin. On two of the three occasions on which this occurred, the participants subsequently rated their experiences as among the five most meaningful and spiritually significant experiences of their lives. These observations suggest that the experiences reported during psilocybin sessions were not merely artifacts of monitor expectation or suggestion.

At the conclusion of the study, the primary monitor and the assistant monitor completed a debriefing questionnaire in which they provided their guesses about the study design. Both monitors believed that a range of psilocybin doses had been administered as well as other active drugs and placebo. Caffeine, dextromethorphan, and diphenhydramine were thought likely to be the other drugs administered, and the primary monitor specifically guessed, based on his previous clinical experience, that methylphenidate had not been administered. Thus, we conclude that the blinding procedures overall were adequately maintained despite the differences in the pharmacological profiles of psilocybin and methylphenidate.

Blood pressure, heart rate, and monitor ratings throughout the session

Both psilocybin and methylphenidate produced significant and orderly time-related effects. For both drugs, the onset of significant blood pressure and monitor-rated effects occurred either at the 30- or 60-min assessment, with the effects generally peaking from 90 to 180 min and decreasing toward pre-drug-administration levels over the remainder of the session (Fig. 1). Heart rate increased by about 10 bpm for both drugs and remained significantly elevated over the pre-drug value throughout the session. The volunteers were rated as showing very low sleepiness/ sedation and restlessness during sessions, with no differences between the psilocybin and methylphenidate conditions (Table 1). The volunteers had a significantly greater number of minutes talking with the monitors after methylphenidate than psilocybin (72 vs 51 min, during the 6 h after capsule ingestion), although after psilocybin they had more physical contact (e.g., handholding) with the monitor (24 vs 58 min) and higher peak ratings of stimulation/ arousal and spontaneous motor activity (Fig. 2; Table 1). It is noteworthy that, during psilocybin sessions, the participants were rated as being less responsive to questions, further from ordinary reality, and showing greater emotionality as reflected in peak ratings of tearing/crying, anxiety/ fearfulness, joy/intense happiness, and peace/harmony (Fig. 2; Table 1).

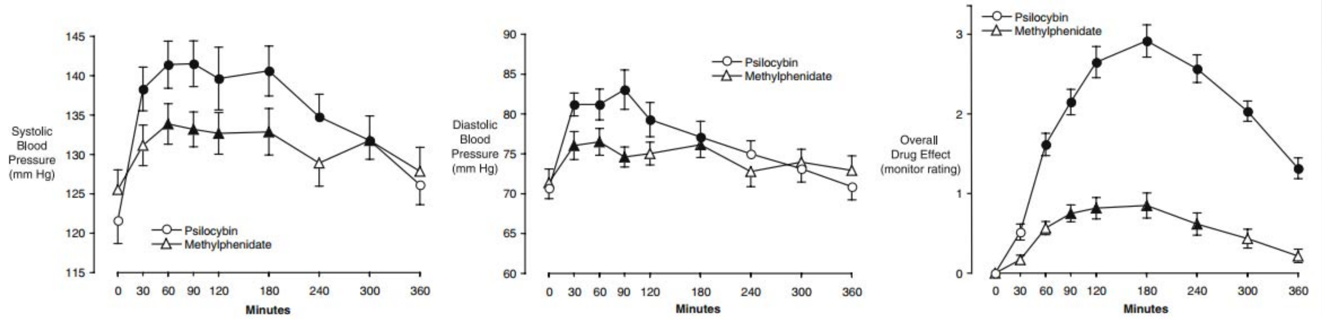

Fig. 1 Within-session time-course of psilocybin and methylphenidate effects. Blood pressure (systolic and diastolic) and monitor ratings (mean of overall drug effect) as a function of time since capsule ingestion (time 0=before drug administration). *Data points* are means with *brackets* showing ±1 SEM (*N*=30) *Filled data* points indicate a significant difference (Tukey HSD) from pre-administration of the drug (time 0). The figure shows that, compared to methylphenidate, psilocybin produced modestly higher elevations in blood pressure but substantially higher monitor rating of overall drug effect.

Table 1. Monitor ratings of volunteer behavior and mood throughout the session.

Rated description	Methylphenidate	Psilocybin	*P* value
Peak effects (maximum score=4)			
Overall drug effect	1.10 (0.15)	3.13 (0.16)	<0.001
Sleepiness/sedation	0.17 (0.07)	0.10 (0.05)	N.S.
Unresponsive to questions	0.07 (0.05)	0.58 (0.20)	<0.05
Anxiety or fearfulness	0.42 (0.09)	1.05 (0.17)	<0.01
Stimulation/arousal	0.68 (0.12)	1.42 (0.26)	<0.001
Distance from ordinary reality	1.12 (0.16)	3.12 (0.14)	<0.001
Ideas of reference/paranoid thinking	0 (0)	0.17 (0.09)	N.S.
Yawning	0.05 (0.03)	1.18 (0.23)	<0.001
Tearing/crying	0.77 (0.13)	1.38 (0.21)	<0.001
Nausea	0.12 (0.06)	0.42 (0.11)	<0.01
Spontaneous motor activity	0.53 (0.17)	1.02 (0.23)	<0.05
Restless/fidgety	0.18 (0.07)	0.27 (0.08)	N.S.
Joy/intense happiness	0.63 (0.15)	2.03 (0.22)	<0.001
Peace/harmony	0.92 (0.15)	1.90 (0.20)	<0.001
Total duration in minutes (maximum score=360)			
Talking with monitor	72.0 (4.8)	50.9 (2.2)	<0.001
Total speech	122.2 (10.7)	106.0 (10.7)	N.S.
Non-speech vocalization[a]	2.2 (1.3)	16.1 (4.5)	<0.01
Physical contact with monitor[b]	23.7 (4.7)	57.6 (8.0)	<0.001
Sleep	0.5 (0.3)	0.2 (0.2)	N.S.
Strong anxiety	0.7 (0.3)	5.6 (2.7)	N.S.

N.S. not significant
[a] For example, humming, sighs, laughter
[b] For example, reassuring touch

Drug effect and mysticism measures assessed 7 h after drug administration

Hallucinogen-sensitive questionnaires

The three questionnaires developed for sensitivity to hallucinogenic drugs showed differences between psilocybin and methylphenidate (Table 2). All six scales of the Hallucinogen Rating Scale, all three scales on the APZ Questionnaire, and the LSD scale of the ARCI were significantly higher after psilocybin than after methylphenidate. These differences reflect the fact that, after psilocybin, the participants experienced alterations in mood, affect, and cognition typical of hallucinogenic drugs. These included perceptual changes (e.g., visual pseudo-hallucinations, illusions, and synesthesias), labile moods (e.g., feelings of transcendence, grief, joy, and/or anxiety), and cognitive changes (e.g., sense of meaning and/or ideas of reference).

A mixed pattern of results occurred on the other scales of the ARCI. The PCAG subscale, which is sensitive to sedative drugs, was higher after psilocybin. It is interesting to note that the two stimulant scales showed opposite effects. The amphetamine scale (A), which was designed to show dose-related sensitivity to amphetamine, was significantly higher after psilocybin than after methylphenidate. However, the benzedrine group scale (BG), which measures amphetamine-induced increases in self-control, efficiency, and concentration, was significantly higher after methylphenidate than after psilocybin. Finally, the morphine-benzedrine group (MBG) scale, which is considered a measure of drug-induced euphoria, did not differ significantly between the drug conditions.

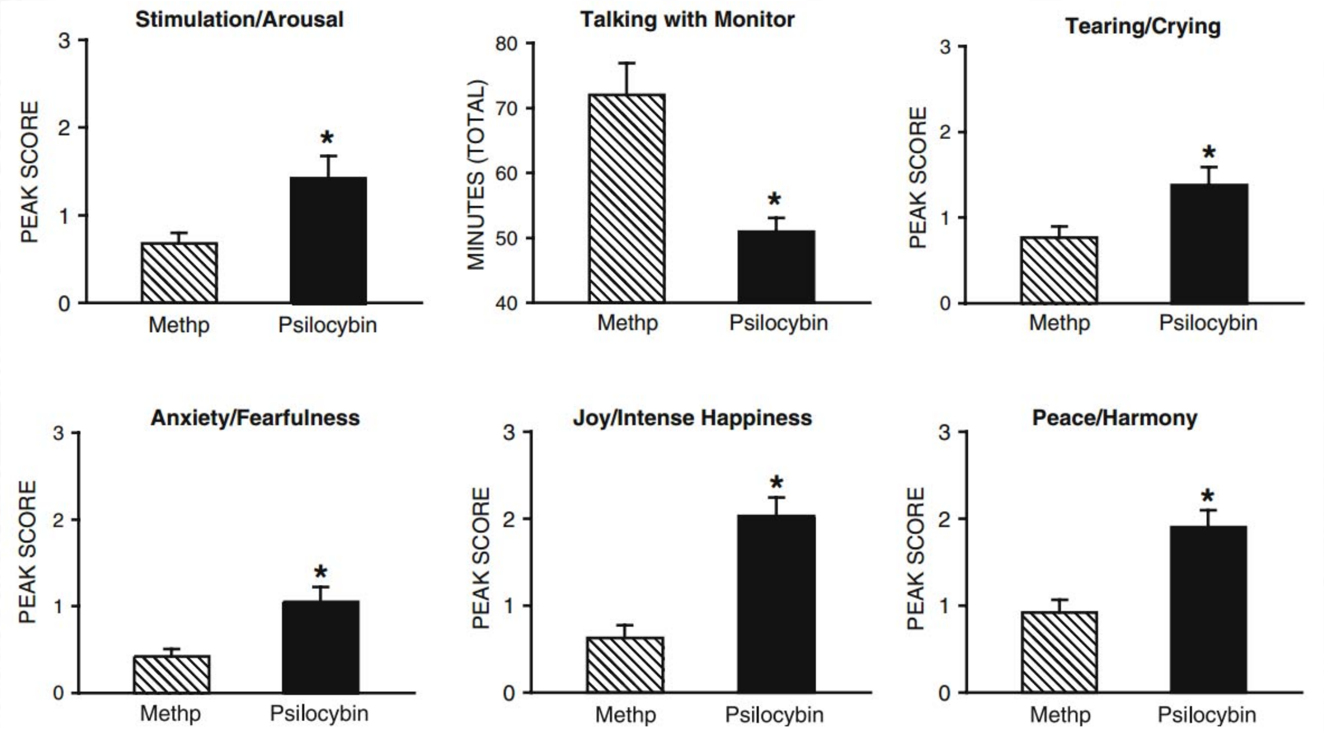

Fig. 2 Monitor ratings during sessions. *Bars* are mean ratings with 1 SEM shown in *brackets* (*N*=30). *Asterisks* indicate a significant difference between the methylphenidate (*Methp*) and psilocybin conditions. Maximum possible rating=4.

Table 2. Volunteer ratings on three drug-sensitive questionnaires completed 7 h after drug administration.

Questionnaire	Subscale description	Methylphenidate	Psilocybin	*P* value
Hallucinogen Rating Scale (4=maximum)	Intensity	1.38 (0.14)	2.79 (0.12)	<0.001
	Somaesthesia	0.91 (0.10)	1.92 (0.11)	<0.001
	Affect	1.16 (0.10)	2.16 (0.10)	<0.001
	Perception	0.54 (0.11)	2.07 (0.14)	<0.001
	Cognition	1.03 (0.14)	2.54 (0.15)	<0.001
	Volition	1.39 (0.06)	1.77 (0.07)	<0.001
APZ Questionnaire	OSE (oceanic boundlessness)	3.30 (0.50)	8.00 (0.45)	<0.001
	AIA (dread of ego dissolution)	1.03 (0.21)	5.03 (0.74)	<0.001
	VUS (visionary restructuralization)	3.70 (0.59)	8.87 (0.47)	<0.001
Addiction Research Center Inventory (ARCI)	PCAG (sedative)	4.83 (0.41)	7.27 (0.58)	<0.001
	BG (amphetamine/self-control)	5.83 (0.38)	4.57 (0.32)	<0.05

Measures of mystical experience

At 7 h after capsule administration, the volunteers also completed two questionnaires designed to assess primary mystical experiences based on classic phenomenological descriptions from the psychology of religion (Table 3). The total score and all three empirically derived factors of the Mysticism Scale and all seven scales on States of Consciousness Questionnaire were significantly higher after psilocybin than after methylphenidate. Based on *a priori* criteria, 22 of the total group of 36 volunteers had a "complete" mystical experience after psilocybin (ten, nine, and three participants in the first, second, and third session, respectively) while only 4 of 36 did so after methylphenidate (two participants each in the first and second sessions).

Table 3. Volunteer ratings on two mystical experience questionnaires completed 7 h after drug administration.

Questionnaire	Subscale description	Methylphenidate	Psilocybin	*P* value
Mysticism Scale	Interpretation	70.6 (4.5)	96.1 (3.3)	<0.001
	Introvertive	66.9 (4.4)	96.3 (2.8)	<0.001
	Extrovertive	37.2 (3.2)	59.7 (2.9)	<0.001
	Total	174.7 (11.3)	252.1 (8.5)	<0.001
States of Consciousness Questionnaire[a]	Internal unity	0.25 (0.05)	0.73 (0.05)	<0.001
	External unity	0.21 (0.05)	0.66 (0.06)	<0.001
	Sacredness	0.36 (0.05)	0.80 (0.04)	<0.001
	Intuitive knowledge	0.30 (0.05)	0.72 (0.05)	<0.001
	Transcendence of time and space	0.27 (0.05)	0.76 (0.04)	<0.001
	Deeply felt positive mood	0.38 (0.04)	0.77 (0.05)	<0.001
	Ineffability	0.29 (0.05)	0.81 (0.05)	<0.001

Data are mean scores with one SEM shown in parentheses (*N*=30)
N.S. not significant
[a] For States of Consciousness Questionnaire, data are expressed as a proportion of the maximum possible score

Measures assessed 2 months post-sessions

Persisting Effects Questionnaire (2 months post-sessions)

As shown in Table 4, compared to methylphenidate, psilocybin produced significantly greater elevations in ratings of positive attitudes, mood, social effects, and behavior; the negative ratings of these same dimensions were very low and did not differ across the drug conditions. This questionnaire also included ratings of the personal meaningfulness and spiritual significance of the experience and whether the experience changed their sense of well being or life satisfaction. Table 4 shows that these ratings were significantly higher after psilocybin than after methylphenidate. It is remarkable that 67% of the volunteers rated the experience with psilocybin to be either the single most meaningful experience of his or her life or among the top five most meaningful experiences of his or her life (Fig. 3). In written comments, the volunteers judged the meaningfulness of the experience to be similar, for example, to the birth of a first child or death of a parent. Thirty-three percent of the volunteers rated the psilocybin experience as being the single most spiritually significant experience of his or her life, with an additional 38% rating it to be among the top five most spiritually significant experiences. In written comments about their answers, the volunteers often described aspects of the experience related to a sense of unity without content (pure consciousness) and/or unity of all things. After methylphenidate, in contrast, 8% of volunteers rated the experience to be among the top five (but not the single most) spiritually significant experiences. Seventy-nine percent of the volunteers rated that the psilocybin experience increased their current sense of personal well being or life satisfaction "moderately" (50%) or "very much" (29%), in contrast to 17 and 4%, respectively, after methylphenidate. No volunteer rated either the psilocybin or methylphenidate experience as having decreased their sense of well being or life satisfaction.

Table 4. Volunteer ratings and community observer ratings completed 2 months after sessions.

Outcome measures	Description	Methylphenidate	Psilocybin	*P* value
Persisting Effects Questionnaire (volunteer ratings)[a]	Positive attitudes about life and/or self	22.8 (4.5)	55.0 (5.0)	<0.001
	Negative attitudes about life and/or self	0.3 (0.1)	0.5 (0.3)	N.S.
	Positive mood changes	16.0 (3.5)	39.2 (5.3)	<0.001
	Negative mood changes	0.6 (0.5)	1.5 (0.7)	N.S.
	Altruistic/positive social effects	17.3 (4.4)	46.6 (5.5)	<0.001
	Antisocial/negative social effects	0.3 (0.2)	0.7 (0.5)	N.S.
	Positive behavior changes	29.2 (6.5)	60.0 (4.8)	<0.001
	Negative behavior changes	1.7 (1.2)	0 (0)	N.S.
	How personally meaningful was the experience?	3.42 (0.35)	6.54 (0.22)	<0.001
	How spiritually significant was the experience?	2.63 (0.22)	4.79 (0.26)	<0.001
	Did the experience change your sense of well being or life satisfaction?	+0.79 (0.18)	+2.04 (0.17)	<0.001
Community observer ratings of changes in participants’ behavior and attitudes[b]	Positive change score	-0.03 (0.68)	2.42 (0.7)	<0.01

Data are mean ratings with one SEM shown in parentheses
N.S. Not significant
[a] For Persisting Effects Questionnaire, data on attitude, mood, social, and behavior changes are expressed as percentage of maximum possible score, and data for the last three questions are raw scores; for volunteer ratings, *N*=24 (cf., "Materials and methods")
[b] For ratings by community observers, data are mean positive change scores; for observer ratings, *N*=26 (cf., "Materials and methods")

Personality and affect

None of the factors on the two widely used questionnaires assessing five factors of personality (NEO and PI-R) and measures of general positive and negative affect (PANAS-X) was differentially affected by psilocybin. At screening and at 2 months after session 1, there were no significant differences between the group that received psilocybin on the first session (*N*=15) and the group that received methylphenidate on the first session (*N*=15). Furthermore, within the latter group, there were no significant changes from post-session 1 to post-session 2.

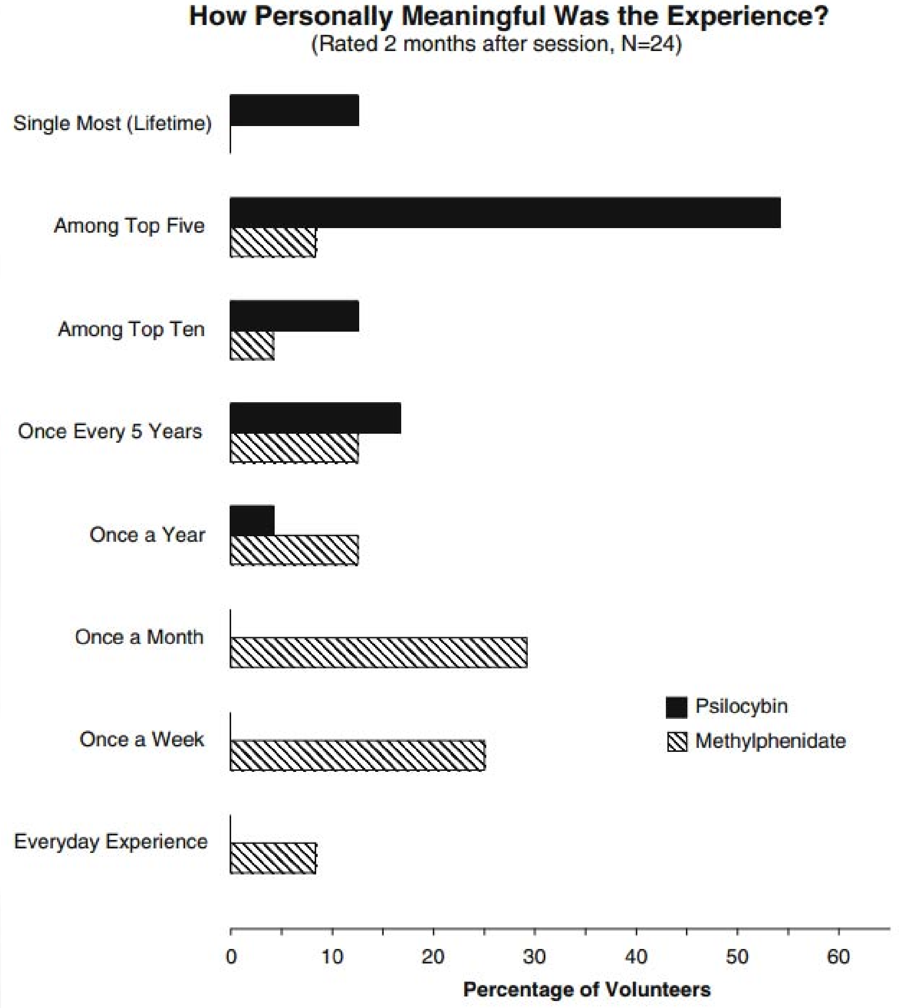

Fig. 3 Percentage of volunteers who endorsed each of eight possible answers to the question "how personally meaningful was the experience?" on a questionnaire completed 2 months after the session (*N*=24)

Lifetime assessment of mystical experience and spirituality

Two additional questionnaires completed 2 months after each session provided lifetime measures of mystical experiences (Mysticism Scale) and spirituality (Spiritual Transcendence Scale). As with the measures of personality and affect, there were no significant differences at screening between the group that received psilocybin on the first session (*N*=15) and the group that received methylphenidate on the first session (*N*=15). As shown in Fig. 4, at 2 months after the first session, lifetime mystical experience and spiritual transcendence scores were significantly higher in the group that received psilocybin on the first session than the group that received methylphenidate on the first session. At 2 months after the second session, the scores in the group that received psilocybin on the second session increased significantly on both measures. As expected, because these scores reflect *lifetime* measures, these scores did not decrease after the second session in the group that received psilocybin on the first session.

Community observer ratings of changes in participants' and behavior and attitudes

Table 4 shows that, compared to methylphenidate, psilocybin sessions were associated with small but significant positive changes in the participants' behavior and attitudes.

Fear, anxiety/dysphoria, and ideas of reference/paranoia

According to monitor ratings, post-session ratings and written comments by the monitors and the participants, and post-session interviews with the participants, many participants reported mild or moderate anticipatory anxiety at the beginning of sessions. In post-session ratings, 11 of the 36 total volunteers after psilocybin and none after methylphenidate rated on the States of Consciousness Questionnaire their "experience of fear" sometime during the session to be "strong" or "extreme." Four volunteers (all of whom had high post-session fear ratings) reported that their entire session was dominated by anxiety or unpleasant psychological struggle (i.e., dysphoria). Four others (again, all of whom had high post-session fear ratings) reported that a significant portion of their session was characterized by anxiety/dysphoria. Although the onset of episodes of notable anxiety/dysphoria was most likely to occur shortly after onset of drug effect, there were occasions on which onset occurred later in the session when drug effects were subsiding. Anxiety/dysphoria occurred when psilocybin was administered on the first (two participants), second (four participants), and third (two participants) sessions, suggesting that longer preparation time and being unblinded to psilocybin administration were not protective. Six of the eight volunteers with a notable anxiety/dysphoria response had mild, transient ideas of reference/paranoid thinking sometime during the 6 h after psilocybin administration. These effects were readily managed with reassurance and did not persist beyond the session. Two of the eight volunteers compared the experience to being in a war and three indicated that they would never wish to repeat an experience like that again. Despite these psychological struggles, most of these participants rated the overall experience as having personal meaning and spiritual significance and no volunteer rated the experience as having decreased their sense of well being or life satisfaction.

Discussion

The present double-blind study shows that psilocybin, when administered under comfortable, structured, interpersonally supported conditions to volunteers who reported regular participation in religious or spiritual activities, occasioned experiences which had marked similarities to classic mystical experiences and which were rated by volunteers as having substantial personal meaning and spiritual significance. Furthermore, the volunteers attributed to the experience sustained positive changes in attitudes and behavior that were consistent with changes rated by friends and family.

The present study advances the empirical analysis of mystical experience. From a scientific perspective, most of what is known about mystical or religious experience is based on descriptive characterization of spontaneously occurring experience (Stace 1960; Spilka *et al*. 2005). Rigorous attempts to prospectively experimentally manipulate such experiences have generally been associated with only modest effects (e.g., Hood *et al*. 1990; Spilka *et al*. 2005). Although there are anecdotal reports from the clinical research in the 1960s of hallucinogens occasioning religious experiences, even when administered in a secular setting (Smith 1964; Masters and Houston 1966; Dobkin de Rios and Janiger 2003), a systematic study of such effects has been almost nonexistent. The most relevant study was one in which theological seminary students received either 30 mg psilocybin (ten participants) or 200 mg nicotinic acid (ten participants) in a group setting during a religious service (the Good Friday Experiment, Pahnke 1963; 1967; Doblin 1991). The participants who received psilocybin showed significant elevations on the Pahnke Mystical Experience Questionnaire and reported positive changes in attitudes and behavior at 6 months and at 25-year followup. Those results are consistent with the present study, which also demonstrated sustained increases on two closely related outcome measures (Pahnke-Richards Mystical Experience Questionnaire and Persisting Effects Questionnaire). Significant limitations of the Pahnke study were that the participants were explicitly told that some would receive psilocybin and some would be controls, and that it was conducted in a group setting. These features resulted in the double-blind being quickly broken during the session, which presumably contributed to the assessed differences between the groups (Doblin 1991; Wulff 1991; Smith 2000). The present study represents an important extension of the Pahnke study using better blinding and comparison control procedures, assessment of effects in individual participants unconfounded by group interactions, empirically validated measures of mystical experience (the Mysticism Scale and the Spiritual Transcendence Scale), and assessment of effects by community observers. The credibility of the blinding procedure is reflected in the facts that the debriefing interviews with the monitors at the end of the study indicated that they remained unaware of the study design and that some volunteers rated their experience during the methylphenidate session as being among the most personally meaningful experiences of their lives (Fig. 3).

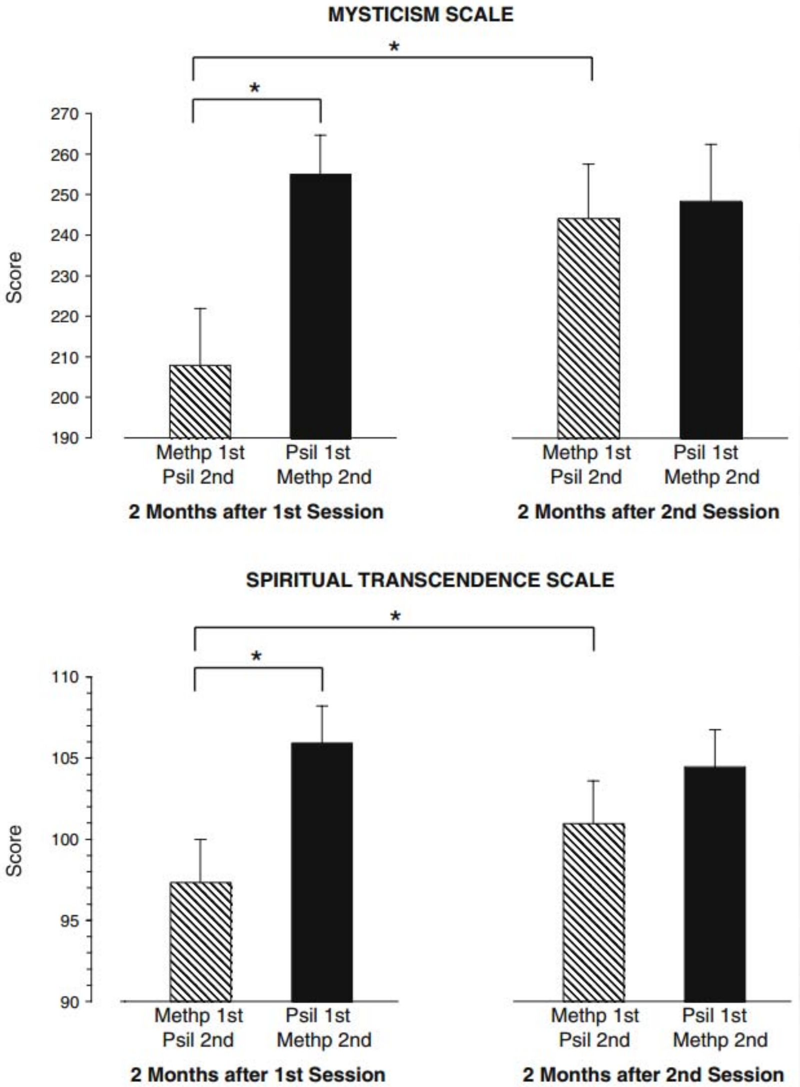

Fig. 4 Lifetime mystical experience (Mysticism Scale) and spirituality (Spiritual Transcendence Scale) scores 2 months after the first session (*left two columns*) and 2 months after the second session (*right two columns*) in two groups of participants. One group (*N*=15) received methylphenidate on the first session and psilocybin on the second session (*Methp 1st, Psil 2nd*) and the other group (*N*=15) received the reverse order (*Psil 1st, Methp 2nd*). Bars are means with *brackets* showing one SEM. *Asterisks* indicate a significant difference between the conditions.

The proportion of volunteers who fulfilled Pahnke's criteria for having a "complete" mystical experience (61%, 22 of 36) is somewhat higher than the 30-40% reported by Pahnke in the Good Friday Experiment (cf. Pahnke 1967, p 67). It seems likely that the greater preparation time (at least 8 versus 3 h in the Pahnke study) and the differences in context (individual sessions with an eye mask and music in an aesthetic room verses the Pahnke study conducted in a group setting with 30 individuals, some of whom were acting bizarrely) likely contributed to this difference. The present study provides no evidence that preparation beyond that given before the first session produced an increase in the incidence of a mystical experience (i.e., on the first, second, and third session, respectively, 67, 60, and 50% of participants who received psilocybin met the criteria for a complete mystical experience) or a decrease in the incidence of anxiety/dysphoria.

The extent to which the study population limits the generalizability of the results is unknown. The participants in this study were hallucinogen-naïve, well educated, psychologically stable, and middle-aged adults, who reported regular participation in religious or spiritual activities. In particular, it seems plausible that the religious or spiritual interest of the participants may have increased the likelihood that the psilocybin experience would be interpreted as having substantial spiritual significance and personal meaning. It is also unknown how the hallucinogen-naïve status of the participants affected either the intensity or qualitative interpretation of the experience. Recruiting volunteers without histories of use avoided the problem of participant selection bias in which individuals who had previously had positive experiences with hallucinogens would have been most likely to participate. However, it is also possible that the novelty of the experience in hallucinogen-naïve individuals enhanced both the intensity and the personal and spiritual significance of the experience.

An important finding of the present study is that, with careful volunteer screening and preparation and when sessions are conducted in a comfortable, well-supervised setting, a high dose of 30 mg/70 kg psilocybin can be administered safely. It is also noteworthy that, despite meetings and prior sessions with monitors ranging from 8 h (when psilocybin was administered on the first session) up to 24 h (when psilocybin was administered on the third session) of contact time, 22% (8 of 36) of the volunteers experienced a period of notable anxiety/dysphoria during the session, sometimes including transient ideas of reference/ paranoia. No volunteer required pharmacological intervention and the psychological effects were readily managed with reassurance. The primary monitor remained accessible via beeper/phone to each volunteer for 24 h after each session, but no volunteer called before the scheduled follow-up meeting on the next day. The 1-year follow-up is ongoing but has been completed by most volunteers (30 of 36). In that follow-up, an open-ended clinical interview reflecting on the study experiences and current life situation provides a clinical context conducive to the spontaneous reporting of study-associated adverse events. To date, there have been no reports of persisting perceptional phenomena sometimes attributed to hallucinogen use or of recreational abuse of hallucinogens, and all participants appear to continue to be high-functioning, productive members of society.

The results of the present study have implications for understanding the abuse of hallucinogens. Although psilocybin is regulated by the federal government under the most restrictive category (Schedule I) of the Controlled Substances Act, the National Institute on Drug Abuse (2001, 2005) does not consider psilocybin and the other classical hallucinogens to be drugs of "addiction" because they do not produce compulsive drug-seeking behavior as do classic addicting drugs such as cocaine, amphetamine, heroin, and alcohol. This conclusion is consistent with observations that psilocybin and other classic hallucinogens do not maintain reliable drug self-administration in animal laboratory models of drug abuse (Griffiths *et al*. 1980; Fantegrossi *et al*. 2004) and that most recreational users of classical hallucinogens decrease or stop their use over time (National Institute on Drug Abuse 2001). In the present study, psilocybin did not produce a classic euphorigenic profile of effects: measures of anxiety and dysphoria (monitor ratings of anxiety: AIA scale on the APZ Questionnaire, LSD scale on the ARCI) were significantly greater after psilocybin than after methylphenidate. However, the present study also shows that, in some people under some conditions, psilocybin can occasion experiences that are rated as highly valued. This seems a likely mechanism underlying the long-term historical use of psilocybin and other hallucinogens such as DMT within some cultures for divinatory or religious purposes.

While there is no indication that carefully monitored clinical exposure of psilocybin to hallucinogen-naïve volunteers results in subsequent abuse (present study; Gouzoulis-Mayfrank, personal communication; Yensen and Dryer, (1992)[1]; Leuner 1981), the epidemic of hallucinogen abuse in the 1960s raises an important cautionary note. Abuse of hallucinogens can be exacerbated under conditions in which hallucinogens are readily available illicitly and the potential harms to both the individual and society are misrepresented or understated. It is important that the risks of hallucinogen use not be underestimated. Even in the present study in which the conditions of volunteer preparation and psilocybin administration were carefully designed to minimize adverse effects, with a high dose of psilocybin 31% of the group of carefully screened volunteers experienced significant fear and 17% had transient ideas of reference/paranoia. Under unmonitored conditions, it is not difficult to imagine such effects escalating to panic and dangerous behavior. Also, the role of hallucinogens in precipitating or exacerbating enduring psychiatric conditions and long-lasting visual perceptual disturbances should remain a topic of research (Abraham *et al*. 1996; Halpern and Pope 1999).

In conclusion, the present study showed that, when administered to volunteers under supportive conditions, psilocybin occasioned experiences similar to spontaneously occurring mystical experiences and which were evaluated by volunteers as having substantial and sustained personal meaning and spiritual significance. The ability to prospectively occasion mystical experiences should permit rigorous scientific investigations about their causes and consequences, providing insights into underlying pharmacological and brain mechanisms, nonmedical use and abuse of psilocybin and similar compounds, as well as the short-term and persisting effects of such experiences.

The study by Griffiths *et al*. is noteworthy both for the rigorousness of its design and execution, as well as the clarity of its results. It demonstrates that psilocybin can be safely studied in normal human beings who do not have a history of hallucinogenic drug use. As would be expected, during the psilocybin session participants showed perceptual changes and labile mood. It is striking that majority of the participants reported 2 months later that the psilocybin-induced experience was personally very meaningful and spiritually significant. Indeed, most of them rated the psilocybin-induced experience as one of the top five most important experiences in their life. It is especially notable that participants reported that the drug produced positive changes in attitudes and behaviors well after the sessions, and these self-observations were consistent with ratings by friends and relatives. These participants were well-prepared for the psilocybin experience by an experienced monitor, who expressly stated that psilocybin might produce increased personal awareness and insight. However, it is clear that the effects of psilocybin were more than expectancy effects because the active drug control condition (40 mg of methylphenidate) did not produce similar effects on ratings of significance or on measures of spirituality, positive attitude, or behavior.

The term psychedelic, when applied to drugs, implies that the drug experience is "mind-expanding." The paper by Griffiths *et al*. illustrates the accuracy of this description for psilocybin, and I hope that this landmark paper will also be "field-expanding." The report clearly demonstrates that we can objectively study the experiences reported by many to be profoundly spiritual and meaningful, and that we can investigate the long-term positive consequences for the individual's attitudes and behavior. It will open the way to study the neural mechanisms responsible for these drug-altered states of consciousness. It is entirely conceivable that psychotropic agents that produce these experiences may have a role in the treatment of addictive states. Spirituality has long been a major component of the 12- step approach to the treatment of alcoholism and other forms of drug addiction. Although the investigations of LSD for the treatment of alcoholism failed to show any clear-cut significant beneficial effects, the possibility that a spiritual experience, such as that reported in the present study, might be useful cannot be discounted. The set and setting in which the drug is administered may dramatically alter the drug experience. In the present study by Griffiths *et al.*, the set was well-established for a positive experience by the preparatory sessions with the monitor, and the setting was one that was designed to produce an introspective state. This may be an important determinant of the experience and could well alter any possible therapeutic efficacy. The possibility of easing the ennui and anguish of impending death with agents such as psilocybin is also suggested in the study by Kast (1966) and those that are reviewed in the commentary of Professor Nichols. It is likely that psilocybin might have the same salutary effects. This is not an insignificant issue especially considering the large numbers of aging individuals in our society who may be in need of hospice care.

In summary, I hope that this paper by Griffiths *et al*. renews interest in a fascinating and potentially useful class of psychotropic agents. The misuse of these substances that led to their control in Schedule I of the Controlled Substances Act cannot be allowed to continue to curtail their use as tools for understanding the neurobiology of human consciousness, self-awareness, and their potential as therapeutic agents. Personally, I also believe that these drugs have a role in discovering the brain mechanisms underlying feelings of spirituality and that such understanding may lead to our investigation of nonpharmacological means of engendering such states. Ultimately, human consciousness in its ever-changing state is a function of the ebb and flow of neural impulses interacting in the various regions of the brain-the very substrate that drugs such as psilocybin act upon. Understanding the brain mechanisms mediating these effects is clearly within the realm of neuroscience and deserves further intensive investigation. Griffiths *et al*. are to be highly commended for reinvigorating this important area of research.

The decade of the 1960s began the current era of heavy drug use in America, beginning perhaps with Timothy Leary's Pied Piper invitation to, "Turn On, Tune In, Drop Out" (with psychedelic drugs). While fortunately most youths who experimented did not suffer lasting damage, those of us on the mental health front lines at the time saw a number of casualties (Kleber 1967). Eventually, the hippies and the LSD-fueled "Summer of Love" in San Francisco were replaced by motorcycle gangs, amphetamines, and gratuitous violence. Psychedelic drugs receded into a permanent background of US drug use, never going away altogether, but not reaching the same penetration.

Unfortunately, one of the lasting casualties of the street use of these agents was research. Sandoz, the manufacturer of LSD, discontinued supplying it to researchers around 1965, concerned that the company's reputation was being tainted by the illicit use. Even though street chemists supplied the vast majority of the illicit use, the licit supply for research more or less disappeared and so did research funding. Prior to the cessation, research with LSD and other psychedelics was active in a variety of areas: as a potential producer of a model psychosis (it has significant limitations); the nature of hallucinations (it produces more illusions); as a therapeutic agent for trauma and the dying (inadequate data); and as a way to study altered reality states, e.g., Huxley's *The Doors of Perception*, Pahnke's Good Friday Experiment, and *Blum's Utopiates: The Use and Users of LSD-25*. Some of the research was carefully done; in most, the researchers seem to be carried away by the effects of the agents.

This category of agents has many names, each reflecting a different point of view as noted above: psychotomimetics (mimicking psychosis), hallucinogens (producing hallucinations), entheogens (revealing the God within), and psychedelics (mind-manifesting). It is in these last two domains that the findings of the study of Griffiths *et al*. belong to even though they did not use either term.

The authors should be commended for the way they designed and carried out the double-blind project. The design involved using 30 mg/70 kg of psilocybin as the active experimental agent and 40 mg/70 kg of methylphenidate as an active control. All subjects received at least one session with each agent in a counterbalanced method. Great care was taken both to minimize risk to subjects, who were all naïve to this category of drugs, and to be able to separate drug effects from expectancy and possible suggestion bias by the monitors. The blinding was done so carefully that even the experienced monitors misidentified the administered agent approximately one quarter of the time. The extensive time with the monitors both before and after the sessions kept adverse effects such as fear and panic to a minimum although 8 of the 36 subjects described all or most of the psilocybin sessions to be dominated by anxiety or dysphoria. These effects did not persist beyond the session, were handled by reassurance, and apparently were of no lasting negative consequence. None of the methylphenidate subjects reported this response. As far as positive effects were concerned, psilocybin increased measures relating to mystical experiences: 22 of the 36 volunteers had a "complete" mystical experience after psilocybin compared to only 4 of the 36 after methylphenidate. At the 2-month follow-up, 67% rated the psilocybin experience to be either "The single most meaningful experience" of their lives or among the top five most meaningful "experiences." After methylphenidate, 8% of the volunteers rated the experience to be "among the top five most meaningful experiences," with none rating it as the single most meaningful experience. Thus, psilocybin significantly increased subjective reports of such experiences while methylphenidate was associated with them only occasionally and to a much lesser effect.

As far as future research is concerned, this study suggests a number of possibilities, both basic and translational, that should merit NIH support. More information is needed on dose effects, subject differences, and the actions of various selective antagonists. Neuroimaging may shed light on sites and mechanisms of action. It would be interesting to see whether the positive responders to methylphenidate activated similar brain sites as the positive psilocybin responders or different ones, as well as what was happening in the brains of the psilocybin nonresponders. From a translational perspective, experienced clinicians are well aware of the profound role that spiritual reawakening experiences, whether achieved through Alcoholics Anonymous, traditional religious venues, or some life experience, can have on successful outcomes from addictive disorders. Increased knowledge about the neuroscience underpinnings of such transformational events could improve drug abuse treatment. It is necessary to keep in mind, however, that drug-induced states are unlikely to have lasting effects in inadequately prepared individuals, as LSD studies on alcoholism in the 1960s suggested.

The positive findings of the study cannot help but raise concern in some that it will lead to increased experimenting with these substances by youth in the kind of uncontrolled and unmonitored fashion that produced casualties over the past three decades. Such a concern, in view of history, is not unwarranted. Even a proponent of such research, Humphry Osmond, who coined the term "psychedelic," noted, "Psychedelics are instruments and like most of our artifacts are capable of being used well or ill. Unluckily, misuse is at least as likely as good use..."

Any study reporting a positive or useful effect of a drug of abuse raises these same concerns. In this Internet age, however, where youth are deluged with glowing personal reports in chat rooms and web sites as well as detailed information about the various agents and how to use them, it is less likely that a scientific study would move the needle much. Psychedelic drug use has remained in a relatively constant range over the past three decades as various fads have come and gone and enthusiastic personal accounts are balanced by negative reports about casualties. Discovering how these mystical and altered consciousness type states arise in the brain could have major therapeutic possibilities, e.g., treatment of intolerable pain, treatment of refractory depression, amelioration of pain and suffering of the terminally ill, to name but a few, as well as the already noted and needed improvement in treatment of substance abuse and dependence states so that it would be scientifically shortsighted not to pursue them.

Psychedelic drugs such as psilocybin, lysergic acid diethylamide (LSD), mescaline, dimethyltryptamine (DMT), and many others include synthetic chemicals and the active ingredients in psychoactive extracts of plants that have been used since time immemorial for their mind-altering properties. These agents were first employed for religious purposes, evidently to facilitate contact with the supernatural. After the discovery of LSD by Albert Hofmann in the early 1940's, much attention was devoted to the perceptual distortions elicited by LSD and related substances, as well as to the similarity of the drug-induced state to transcendental states reported by mystics of varied religious persuasions.

The different effects elicited by these drugs have led to different names. They are designated "psychotomimetics" because one can reasonably argue that individuals taking the drugs have lost contact with reality and are, hence, psychotic. They are called "hallucinogens" because of the perceptual distortions. However, frank hallucinations - seeing or hearing something that doesn't exist at all in the environment - are rare. Rather, visual and auditory perceptions are notably intensified and altered. Subjects report synesthesia, a seeming transmutation of the senses, e.g., visualizing sound waves upon hearing a loud noise. Humphrey Osmond coined the term "psychedelic" meaning "mind-manifesting" to emphasize the extraordinary change in the sense of self, a feeling of communion with the infinite, a dissolution of ego boundaries with the self, seeming to merge with environment. These are arguably the most remarkable of all the drug effects and may teach us much about neurochemical systems that mediate our sense of consciousness. Hence, I prefer the term psychedelic despite this term's possibly connoting the irresponsible use of these drugs by some in the late 1960s. In the interests of full disclosure, I myself had single sessions each with LSD and DMT well over 40 years ago and experienced the effects described here. Numerous clinical studies with psychedelic drugs were conducted in the 1950s and 1960s. One of the few controlled investigations of the relationship of psychedelic drugs and mystical consciousness was carried out by Walter Pahnke as his doctoral dissertation at Harvard University. He utilized psilocybin, the psychoactive ingredient in the mushroom psilocybe, which for logistic reasons, has been the most widely employed psychedelic drug in clinical research. Psychedelic drugs vary in chemical structure with mescaline, (DOM), and 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy), being phenethylamines that resemble neurotransmitters such as norepinephrine and dopamine. Others, such as psilocybin, LSD, and DMT, contain indole moieties and more closely resemble serotonin. Extensive pharmacologic studies have established that all the drugs, phenethylamines and indoles, exert their actions primarily by mimicking serotonin at one of its receptor subtypes, 5-$HT_{2A,C}$. In the Pahnke "Good Friday" study, groups of ten theological seminary students were administered either 30 mg psilocybin or 200 mg nicotinic acid in a group setting as part of a religious service. Psilocybin consistently elicited a mystical experience not evident with nicotinic acid.

The rampant abuse of psychedelic drugs in the late 1960s led to strict controls with such severe restrictions that clinical and even laboratory research virtually vanished. Griffiths *et al*. now report a rigorous, blinded study of mystical experiences associated with psilocybin. Exquisite care was devoted to the design of the trial to minimize risk to subjects and to discriminate drug effects from the influences of suggestion. Participants were emotionally stable, generally middle-aged college graduates. They received either 30 mg of psilocybin or 40 mg of methylphenidate (Ritalin) per 70 kg, with each subject receiving the two drugs in separate sessions. Most important was the careful preparation with study monitors meeting with subjects on multiple occasions before and after each drug session. Such a setup was designed to diminish the likelihood of panic and to facilitate each subject's acceptance of major changes in consciousness. Subjects were administered an extensive array of questionnaires evaluating potential mystical experiences and they were followed up in depth 2 months later. One striking result was the effectiveness of the blinding procedure, which is often virtually impossible for psychoactive agents. Surprisingly, even the sophisticated monitors mistook one of the drugs for the other in about 25% of the sessions. Thus, the study results are not likely to be contaminated by expectant attitudes and biases of experimenters and/or subjects.

Psilocybin elicited what one would expect, perceptual distortions including visual distortions, feelings of transcendence, and a high incidence of mystical experiences, substantially greater than in the Pahnke study. Particularly impressive was the persistence of influences of psilocybin upon subjects' sense of their selves. When interviewed 2 months after the drug session, subjects reported that psilocybin enhanced their attitudes about life in general, their mood and relationships with others. Most remarkable was the sentiment of two-thirds of the subjects that the psilocybin experience was either the "single most meaningful experience of his/her life or among the top five most meaningful experiences of his/her life."

What are the major take-home messages of the Griffiths *et al*. investigation? The ability of these researchers to conduct a double-blind, well-controlled study tells us that clinical research with psychedelic drugs need not be so risky as to be off-limits to most investigators. Indeed, there were very few adverse events acutely and none at the 2-month and 1-year follow-ups.

The observation that psilocybin reliably elicits a transcendent, mystical state tells us that investigations of these drugs may help us understand molecular alterations in the brain that underlie mystical religious experiences. Religious sensibilities are increasingly prominent throughout the world and often involve "born again" ineffable experiences analogous to psychedelic drug effects. Thus, seeking the "locus of religion" in the brain is by no means fanciful. We already have a hint in evidence that psychedelic drugs act by mimicking serotonin at $5HT_{2A,C}$ receptors. The major serotonin neuronal projections in the brain have their cell bodies in midline brainstem structures called the raphe nuclei, which receive input from neuronal input for the major senses. Accordingly, it is not far-fetched to ascribe to altered serotonin neurotransmission the subjective interconversion of senses that occurs with synesthesia. As the boundaries of our sense of self, our ego, are determined by the integration of sensory perception, it is conceivable that changes in serotonin systems mediate the diffusion of ego boundaries that underlies the transcendent merger of "self with universe" that is reported consistently by mystics of all religious persuasions and occurs often under the influence of psychedelic drugs.

By showing that one can responsibly conduct clinical research with psychedelic drugs and by confirming the mystical influences of these agents, Griffiths *et al*. may help resurrect psychedelic drugs as major tools in probing the molecular bases of consciousness.

The article by Griffiths *et al*. in this issue of Psychopharmacology should make all scientists interested in human psychopharmacology sit up and take notice. It is the first well-designed, placebo-controlled, clinical study in more than four decades to examine the psychological consequences of the effects of the hallucinogenic (psychedelic) agent known as psilocybin. In fact, one would be hard-pressed to find a single study of psychedelics from any earlier era that was as well-done or as meaningful. Perhaps more importantly, despite the notion by many people that psychedelics are nothing more than troublesome drugs of abuse, the present study convincingly demonstrates that, when used appropriately, these compounds can produce remarkable, possibly beneficial, effects that certainly deserve further study.

Although many people seem to believe that "psychedelics" simply appeared during the turbulent 1960s, in fact the use of these materials spans back through many millennia of human history. Ancient substances with names such as *Soma* (India), Kykeon (Greece), and *Teonanacatl* (South America) served for thousands of years as psychopharmacological catalysts in a variety of sacred religious and magical rituals (Nichols 2004; Schultes and Hofmann 1979). Peyote, the ceremonial use of which is now thought by anthropologists to date back at least 5,000 years, is revered as a sacrament by the Native American Church. Ayahuasca, a decoction made from plants that grow in the Amazon basin, is a sacrament used by a syncretic church in Brazil. This church has a small following in the US that has just received a favorable decision by the US Supreme Court allowing them continued use of this material.

The parallel between mystical states and the effects of psychedelic drugs is well-known among those familiar with the literature. Aldous Huxley, in his classic but controversial 1954 book, *The Doors of Perception*, (Huxley 1970) noted the similarity of his own mescaline-induced state to experiences described by mystics and visionaries from a variety of cultures. Perhaps it is not surprising then that the name "entheogen," with the connotation that these materials reveal god within, is becoming increasingly popular among those who continue to use these substances for purposes that are neither medical nor "recreational."

We must, therefore, take note of what has come to be known as the "Good Friday Experiment," carried out by Walter Pahnke for his Ph.D. studies at a small private chapel in Boston. His 1963 Ph.D. dissertation was titled *Drugs and Mysticism. An analysis of the relationship between psychedelic drugs and the mystical consciousness*. He described in an experiment with 20 student volunteers from a local Christian theological seminary. Subjects were given either 30 mg of psilocybin or 200 mg of nicotinic acid as a "placebo." The experiment was carried out in a religious setting during a Good Friday service. Pahnke concluded, "Under the conditions of this experiment, those subjects who received psilocybin experienced phenomena which were indistinguishable from, if not identical with, certain categories defined by our typology of mysticism."

Clearly, these substances have profound effects on human consciousness, and in the 1950s and 1960s, the drug known as LSD was hailed as a revolutionary new technology for psychiatry. LSD was intensively investigated for its medical potential and for possible use as an adjunct to psychotherapy until clinical research was abruptly halted by laws passed in response to concerns over widespread recreational use. Despite studies that involved tens of thousands of patients, using "therapeutic" approaches that employed LSD in a variety of ways, little of clear significance resulted, at least partly due to faulty experimental design and data analysis. As a consequence, a conventional wisdom seems to have developed that psychedelic drugs are generally pretty worthless. But medical technology has advanced in the past four decades; we know quite a bit more about the brain now than we did then, and human experimental methods are certainly much better.

All that being said, there was one indication for the use of psychedelics, particularly LSD, that was reasonably well-documented. Chicago internist Eric Kast first reported in 1964 that some "gravely ill" patients treated with LSD obtained mood elevation and reductions in the need for pain medication that lasted for nearly 2 weeks after the drug, and that some patients "displayed a peculiar disregard for the gravity of their situations" (Kast and Collins 1964). In a subsequent study, he further noted that, "Patients who had been listless and depressed were touched to tears by the discovery of a depth of feeling they had not thought themselves capable" (Kast 1966).

Kast's findings served as the foundation for a series of groundbreaking studies into the value of LSD in the treatment of terminal cancer patients. That work was carried out at the Maryland Psychiatric Research Center in Baltimore, Maryland by Drs. Stanislav Grof, Al Kurland, Walter Pahnke, Sanford Unger, and their colleagues (Grof *et al*. 1973; Pahnke *et al*. 1969, 1970a,b). Significantly reduced need for analgesics and improved mood and quality of life were observed in 60-70% of patients treated with LSD. The treatment response appeared to be correlated with the extent to which the patients experienced a mystical or transcendental state. That is, those who experienced the most profound LSD-induced states seemed to gain the most improvement. The basis for this benefit appeared to be related to a reduced or abolished fear of death, with an attendant reduction in anxiety, which we know affects subjective pain.

What Griffiths *et al*. have done in their present work represents an important extension of Pahnke's "Good Friday" experiment. They have used proper controls, better experimental design, and have provided a better analysis of the experience using more modern instruments. The experiments were not conducted in a church, or in a venue that would lead to a strong expectation of some sort of religious experience. The subjects in the Griffiths *et al*. study were not theology students, but were simply ordinary people with an interest in spiritual things. The work by Griffiths *et al*. demonstrates that, under appropriate experimental conditions, psilocybin occasioned experiences similar to spontaneously occurring mystical states. Most importantly, some of the persisting positive changes in attitudes and behavior reported by subjects were confirmed by independent ratings from community observers such as family members or friends.

The prospects for far-ranging scientific advancement are exciting. We know that psychedelics have powerful effects in many areas of the brain that are critically important for cognition and awareness. Our present understanding is that they act principally by activating serotonin 5-HT$_{2A}$ receptors, especially those densely expressed on the apical dendrites of cortical pyramidal cells, the quintessential computational units within the cortex of the brain. In that respect, psychedelics depolarize these cortical cells, leading one to speculate that they may become more sensitive to low-level signals. That is, perhaps they can do more with less, potentially amplifying processes that are normally running, but which are not generally apparent in everyday awareness.

The science of pharmacology involves perturbing biological systems with chemical modulators (i.e., drugs), the results of which have had profound effects on our understanding of both normal and disease state physiology. Rigorous research with psychedelics may hold the key to understanding the very nature of consciousness, self-awareness, the ability to introspect, and the properties of mind that set us apart from other species.

With such a huge potential impact, is there any good reason why a well-done study like the one reported here by Griffiths *et al*. should appear only once in half a century? Until a related compound, DMT, was studied by Rick Strassman at the University of New Mexico in the mid- 1990s (Strassman and Qualls 1994; Strassman *et al*. 1994; Strassman 1996), no significant work on the clinical effects of psychedelics had appeared in the scientific literature for more than a generation. Perhaps the time has now come to reinvestigate the psychopharmacological properties of psychedelics. Thus, the study by Griffiths *et al*. in this issue could be a watershed event.

Finally, Griffiths *et al*. conclude, "The ability to occasion such experiences prospectively will allow rigorous scientific investigations of their causes and consequences." Indeed.

Towards a science of spiritual experience (Harriet de Wit)

Received: 24 May 2006 / Accepted: 27 May 2006

Harriet de Wit
Department of Psychiatry, The University of Chicago,
MC3077, 5841 S. Maryland Avenue,
Chicago, IL 60637, USA
e-mail: hdew@midway.uchicago.edu

People have long sought meaning and significance in their lives through a variety of spiritual practices including prayer, fasting, chanting, solitude, and meditation. Historically, some of these practices have included the use of certain psychoactive plants. A common theme of these experiences, with or without the aid of psychoactive agents, has been to free oneself of the bounds of everyday perception and thought in a search for universal truths and enlightenment. To a large extent, this type of subjective and uniquely human experience has enjoyed little credibility in the mainstream scientific world and, thus, has been given little scientific attention. However, it may be time now to recognize these extraordinary subjective experiences, even if they are, at present, not directly verifiable by objective measures and even if they sometimes involve claims about ultimate realities that lie outside the purview of science.

The article by Griffiths *et al*. describes one of the first attempts to study these experiences in a systematic scientific investigation of the reportedly profound and sometimes life-altering experiences induced by the powerful hallucinogen psilocybin. Their study is unique in several ways. First, it applies rigorous, modern methods of psychopharmacological research, including use of controlled, double-blind drug administration with a positive control drug and counterbalanced orders, standardized and replicable testing conditions, and sensitive outcome measures. Second, the study was conducted in specially designed environment, where the drug effects could be experienced safely yet unconstrained by an unnecessarily impersonal laboratory or clinical setting. Third, this is the first modern psychopharmacology study to focus, with healthy volunteers, upon experiences of deeply meaningful insights and understanding. Finally, the study is unique in that the investigators have also begun to study the lasting, life-changing effects that have been attributed to such experiences, using systematic follow-up assessments of mood and overt behavioral changes in the participants' lives.

The Editors invited commentaries from four experts to put this study in a larger context. These commentaries by Drs. Solomon Snyder, Charles R. Schuster, Herbert Kleber, and David Nichols provide a context for the study in terms of the history, policy, psychiatry, and future research. They relate this study historically to previous studies with hallucinogens and discuss the implications for drug and drug research policy. They discuss this class of drugs in terms of potentially adverse psychiatric consequences and also in terms of potential therapeutic applications. The commentaries identify important future directions for research on the neurochemistry and neurobiology of these drugs and these experiences. Taken together, these commentaries indicate that the Griffiths *et al*. study will likely take an important place in the history of human psychopharmacology research.

It is time for psychopharmacologists to open their minds and their laboratories to the full domain of human drug experience. We would do well to be wary of our own preconceptions and prejudgments, and to be prepared to consider the entire scope of human experience and behavior as legitimate targets for systematic and ethical scientific investigation. Griffiths *et al*. set an excellent example for such a venture.

Mystical Experiences Occasioned by the Hallucinogen Psilocybin Lead to Increases in the Personality Domain of Openness

Abstract

A large body of evidence, including longitudinal analyses of personality change, suggests that core personality traits are predominantly stable after age 30. To our knowledge, no study has demonstrated changes in personality in healthy adults after an experimentally manipulated discrete event. Intriguingly, double-blind controlled studies have shown that the classic hallucinogen psilocybin occasions personally and spiritually significant mystical experiences that predict long-term changes in behaviors, attitudes and values. In the present report we assessed the effect of psilocybin on changes in the five broad domains of personality - Neuroticism, Extroversion, Openness, Agreeableness, and Conscientiousness. Consistent with participant claims of hallucinogen-occasioned increases in aesthetic appreciation, imagination, and creativity, we found significant increases in Openness following a high-dose psilocybin session. In participants who had mystical experiences during their psilocybin session, Openness remained significantly higher than baseline more than one year after the session. The findings suggest a specific role for psilocybin and mystical-type experiences in adult personality change.

Keywords: hallucinogen; mystical experience; openness; personality; psilocybin; psychedelic.

Psilocybin and other classic hallucinogens with actions mediated at the 5-HT_{2A} receptor site (Glennon *et al.*, 1984; Nichols, 2004) produce a unique profile of subjective effects including robust changes in perception, cognition, affect, volition, and somaesthesia (Isbell, 1959; Wolbach *et al.*, 1962; Rosenberg *et al.*, 1964). In early trials of hallucinogens administered under supportive conditions, 50 - 80% of participants claimed lasting beneficial changes in personality, values, attitudes and behavior (Metzner and Editors, 1963; McGlothlin and Arnold, 1971). Some of the most frequent subjective reports included greater appreciation of music, art and nature, greater tolerance of others, and increased creativity and imagination (McGlothlin *et al.*, 1967). Consistent with these findings, Studerus *et al*. (2010) recently reported that nearly 40% of participants in several laboratory studies of psilocybin claimed positive long-term changes in aesthetic experience and in their relationship with the environment (i.e., nature) following their psilocybin sessions.

The long-term positive impact of hallucinogens may depend on their ability to occasion profound insights and mystical-type experiences (Pahnke, 1963; Doblin, 1991). The core features of *mystical experience*, as defined by Stace (1960) and Hood (2003), are feelings of unity and interconnectedness with all people and things, a sense of sacredness, feelings of peace and joy, a sense of transcending normal time and space, ineffability, and an intuitive belief that the experience is a source of objective truth about the nature of reality. Because such experiences appear to enable individuals to transcend their usual patterns of thinking, feeling, and acting, it is plausible that they could occasion changes in core dimensions of personality. In support of this, a double-blind controlled study by Griffiths *et al*. (Griffiths *et al.*, 2006; Griffiths *et al.*, 2008) demonstrated that a single psilocybin session occasioned mystical experiences associated with positive changes in behaviors, attitudes and values more than a year later. Moreover, independent ratings from participants' romantic partners, coworkers, and friends corroborated the first-person reports. These findings suggest fundamental changes in personal concerns, goals, and identity, which are considered to be important dimensions of personality (e.g., in the framework described in McAdams, 1995). However, the impact of psilocybin-occasioned mystical experience on core personality traits is unknown.

There is general agreement that personality traits are relatively enduring styles of thinking, feeling, and acting (McCrae and Costa, 1997). The most widely accepted model of personality structure is the five-factor model, which describes five broad domains of personality each encompassing many related traits: Neuroticism, Extroversion, Openness, Agreeableness and Conscientiousness (Digman, 1990; McCrae, 2009). Many studies have confirmed that these personality factors are heritable (Bouchard *et al.*, 1990) and reliable across cultures, suggesting a universal human personality structure that is rooted in biology (McCrae and Costa, 1997). Longitudinal studies have shown that individual personality is predominantly stable across the lifespan. Although there are mean-level personality changes after age 30, these shifts are typically gradual and subtle (1 - 2 *T*-score points per decade; Terracciano *et al.*, 2005).

Despite the relatively stable nature of personality, researchers have hypothesized that significant life events could change adult personality quite dramatically. Studies investigating individual differences in personality-trait change have found that certain life experiences are associated with changes in adult personality (see review in Roberts and Mroczek, 2008). For example, personality changes have been associated with divorce (e.g., increases in Extroversion and Openness in women, Costa *et al.*, 2000), remarriage (e.g., decreases in Neuroticism in men, Mroczek and Spiro, 2003), and career success (e.g., decreases in Conscientiousness in individuals who were fired vs. promoted, Costa *et al.*, 2000). However, such correlational studies cannot address the causal link between particular events and subsequent personality change.

Relatively little research has investigated personality change in the laboratory, likely because events that might be expected to change personality are difficult to create under experimental (i.e., randomized or assigned) conditions. Some studies have shown changes in personality after experimental treatment interventions in patients, such as several weeks of antidepressant medication (e.g., Costa *et al.*, 2005) and intensive outpatient counseling for substance abuse rehabilitation (Piedmont, 2001). Personality changes have also been shown in healthy adults after three months of intensive contemplative training in attention- and emotion-regulation (Sahdra *et al.*, 2011). These personality changes, as well as socioemotional and behavioral improvements, were maintained several months after completion of training, suggesting possible long-term benefits.

To our knowledge, no study has prospectively demonstrated personality change in healthy adults after an experimentally manipulated discrete event. Although it has been speculated that treatment with classic hallucinogens could be a method for occasioning dramatic and rapid personality change (Unger, 1964), a controlled study of LSD in healthy volunteers failed to find significant changes in a large battery of empirical measures of personality, aesthetic sensitivity, and creativity six months after LSD sessions (McGlothlin *et al.*, 1967). Nevertheless, these investigators confirmed the subjective claims of long-term change frequently reported in uncontrolled trials.

The subjective claims of hallucinogen-occasioned long-term changes (Metzner and Editors, 1963; McGlothlin *et al.*, 1967; McGlothlin and Arnold, 1971; Studerus *et al.*, 2010) appear to align with the personality construct of Openness, which encompasses aesthetic appreciation and sensitivity, imagination and fantasy, and broad-minded tolerance of others' viewpoints and values. The present report combines data from two double-blind controlled studies of psilocybin (Griffiths *et al.*, 2006; Griffiths *et al.*, 2011) to analyze changes in Openness and the other four broad personality domains using the NEO Personality Inventory (Costa and McCrae, 1992). Personality change was assessed 1 - 2 months after a high-dose psilocybin session and again more than one year later to determine the persistence of personality change. Consistent with previous results indicating a correlation between mystical experiences during the session and long-term spiritual significance and personal meaning attribution (Griffiths *et al.*, 2008), we hypothesized that mystical experiences during the psilocybin session would lead to enduring increases in Openness.

Methods

Participants

Recruitment methods and screening procedures were similar across the two studies. Participants were recruited from the local community by flyers announcing "a study of states of consciousness brought about by psilocybin, a naturally occurring psychoactive substance used sacramentally in some cultures". The first phase of screening involved a scripted telephone interview, which was used to pre-screen for the major inclusion/exclusion criteria. Common reasons for not passing the telephone screen included distance from study site, extensive prior hallucinogen use, and inability to make the time commitment required for participation. Individuals who passed the telephone screen (approximately 20% of those screened) were evaluated in-person for inclusion/exclusion criteria and medical and psychiatric health, as described previously for human research with classic hallucinogens (Johnson *et al.*, 2008). The inclusion/exclusion criteria were similar across the two studies, although participants in Study 2 were permitted to have limited prior experience with hallucinogens (Griffiths *et al.*, 2011). The single participant in Study 2 who had prior lifetime experience with psilocybin was excluded from the present analyses. In addition, 1 participant in Study 1 (Griffiths *et al.*, 2006) had incomplete personality data and was excluded. Thus, the present analyses included 52 hallucinogen-naïve participants (Table 1). Participants were generally well educated (54% had post-graduate degrees) and spiritually active (90% regularly participated in religious services, discussion groups, prayer, or meditation).

Participants did not receive monetary compensation but generally reported being motivated by curiosity about the effects of psilocybin and the opportunity for extensive self-reflection. The Institutional Review Board of the Johns Hopkins University School of Medicine approved the studies, and all participants gave their informed consent before participation.

Psilocybin sessions

Dose conditions - Participants completed two to five 8-hour drug sessions, with consecutive sessions separated by at least 3 weeks. Participants were informed that they would receive a "moderate or high dose" of psilocybin during one of their drug sessions, but neither the participant nor the session monitors knew when this session would occur. In Study 1 (Griffiths *et al.*, 2006), each participant received psilocybin (30 mg/70 kg body weight) on one session and an active control drug, methylphenidate (40 mg/70 kg), on the other one or two sessions. In Study 2 (Griffiths *et al.*, 2011), each participant received four doses of psilocybin (5, 10, 20 and 30 mg/70 kg) in ascending or descending order (50% random assignment) across four sessions, with a fifth placebo session quasi-randomly inserted in the sequence. In the present report, we analyzed mystical experiences and changes in personality associated with the high-dose (30 mg/70 kg) psilocybin session.

Table 1 - Demographic and Personality Variables at Screening.

	Study 1	Study 2
Age at study entry (years)	46 (24-64)	46 (29-62)
Sex	14 M, 21 F	8 M, 9 F
Education	4.2 (2-5)	4.0 (2-5)
Mysticism Scale - Lifetime	215 (184-283)	216 (124-282)
NEO Personality Inventory		
Neuroticism	41.8 (26.4-64.6)	46.1 (19.3-61.3)
Extroversion	55.3 (31.3-76.4)	52.1 (34.0-78.0)
Openness	65.4 (42.1-80.3)	62.7 (45.6-83.8)
Agreeableness	55.7 (41.0-75.1)	55.1 (37.2-72.6)
Conscientiousness	51.0 (22.7-80.6)	51.7 (32.9-72.1)

Note: The table presents mean values (with ranges in parentheses) for hallucinogen-naïve participants with complete personality data (*n* = 35 in Study 1; *n* = 17 in Study 2). Educational achievement was scored on the following scale: 1 = high school diploma; 2 = some college; 3 = college degree; 4 = some graduate study; 5 = graduate degree. Mystical experiences across the lifetime were quantified as total score on the Hood Mysticism Scale at screening (Hood *et al.*, 2001). Personality was assessed using a computer-based version of the revised NEO Personality Inventory (Costa and McCrae, 1992). No significant study-group differences in demographic or personality variables were evident at screening (*p*s > 0.10).

Session protocol - Participants received extensive preparation and met with session monitors for at least eight hours on several different occasions prior to their first drug session, in line with recommendations for hallucinogen research (Johnson *et al.*, 2008). The drug was orally administered in capsule form with 100 mL water at the beginning of each session. During the session, participants were encouraged to lie down on a couch, use an eye mask to block external visual distraction, wear headphones through which a music program was played, and focus their attention on their inner experiences.

Measures

NEO Personality Inventory (NEO-PI) - Personality was assessed at screening, 1 - 2 months after each drug session, and approximately 14 months after the last drug session using a computer-based version of the revised NEO-PI (Costa and McCrae, 1992). This 240- item instrument measures the five factors of personality and the six facets that define each factor. The facets of Openness are Fantasy (e.g., "I have a very active imagination"), Aesthetics (e.g., "I am intrigued by patterns I find in art and nature"), Feelings (e.g., "I experience a wide range of emotions and feelings"), Ideas (e.g., "I often enjoy playing with theories or abstract ideas"), Values (e.g., "I consider myself broad-minded and tolerant of other people's lifestyles"), and Actions (e.g., "I think it's interesting to learn and develop new hobbies"). Items were answered on a 5-point scale ranging from *strongly disagree* to *strongly agree*, and raw scores were standardized as *T* scores (*M* = 50, *SD* = 10) using the combined-sex norms reported in the NEO PI-R manual.

States of Consciousness Questionnaire (SOCQ) - Mystical-type phenomena during the drug sessions were assessed using 43 mystical-experience items embedded within a 100- item instrument, the States of Consciousness Questionnaire (SOCQ), which assesses phenomenological content during altered states of consciousness (Griffiths *et al.*, 2006). The mystical-experience items have been shown to be sensitive to the effects of psilocybin (Pahnke, 1963; Doblin, 1991; Griffiths *et al.*, 2006; Griffiths *et al.*, 2011) and other hallucinogens (Turek *et al.*, 1974; Richards *et al.*, 1977). The SOCQ was administered after each session (approximately 7 hours after capsule administration). Items were answered on a 6-point scale ranging from 0 (*none, not at all*) to 5 (extreme, more than ever before in my life and stronger than 4). Data on each of the following six subscales were expressed as percentage of maximum possible score: unity; transcendence of time and space; ineffability and paradoxicality; sacredness; noetic quality; and positive mood. Consistent with previous research (Griffiths *et al.*, 2006), a "complete mystical experience" was defined as having a score of 60% or higher on each subscale. A total score was also calculated as the mean across all items in the six subscales.

Mysticism Scale - The Mysticism Scale was originally developed to assess mystical experiences across the lifetime and has been validated in several studies, including cross-culturally (Hood, 1975; Hood *et al.*, 2001; Hood, 2003). Items were answered on a 9-point scale ranging from -4 (this description is extremely not true of my own experience) to +4 (this description is extremely true of my own experience). Total score (sum across 32 items) was used to quantify lifetime mystical experiences at screening (see Table 1). Additionally, a modified version of the Mysticism Scale was used to assess mystical effects during the drug sessions. Participants completed the experience-specific version approximately 7 hours after capsule administration and answered the items in reference to their experiences since receiving the capsule that morning.

APZ - The APZ is a 72-item yes/no questionnaire designed to assess altered states of consciousness, including those produced by hallucinogens (Dittrich, 1998). The three scales on the APZ are OSE ("oceanic boundlessness"; this scale assesses phenomena such as unity, bliss, and transcendence of time and space); VUS ("visionary restructuralization"; this scale assesses visual pseudo-hallucinations, illusions, and synaesthesias); and AIA ("dread of ego dissolution"; this scale assesses dysphoric feelings such as anxiety, fear, and feeling trapped). Data on each scale were expressed as percentage of maximum possible score.

Analysis

We combined data from two double-blind psilocybin studies to achieve greater statistical power to detect personality change at the group level and to examine personality change in sub-groups of individuals who differed in mystical-type psilocybin effects. Because Study 2 involved multiple doses of psilocybin in addition to the single high dose used in Study 1, it was not possible to completely isolate the high-dose session in Study 2. However, the session protocol implemented in Study 2 was identical to that used in Study 1. Furthermore, changes in personality following the high-dose session were always assessed within 1 - 2 months of the high-dose session and before any subsequent session.

We hypothesized that mystical experiences during the psilocybin session, as measured by the SOCQ, would lead to increases in Openness. We investigated this prediction using three analysis approaches (all analyses were conducted in SPSS version 18.0). First, we used multivariate repeated measures analysis of variance (ANOVA) to analyze changes in Openness and the other four NEO-PI factors (Neuroticism, Extroversion, Agreeableness, and Conscientiousness) from screening to post-test (1 - 2 months after the high-dose psilocybin session). After confirming that Openness changed significantly following the high-dose session, we calculated Pearson's linear correlations between changes in Openness and session-day measures (the SOCQ, the Mysticism Scale, the OSE, the VUS, and the AIA). We then confirmed via regression analysis that mystical experience, as measured by the SOCQ, was a significant predictor of changes in Openness. Specifically, we conducted a series of linear regression analyses that tested the predictive power of the SOCQ above and beyond the predictive power of the four questionnaire measures that also correlated with Openness change (the Mysticism Scale, the OSE, the VUS, and the AIA). In each of four models (one model for each questionnaire), we tested the following predictors of Openness at post-test in a step-wise manner: 1) Openness at screening, 2) an alternate questionnaire measure (e.g., total score on the Mysticism Scale), and 3) mystical score on the SOCQ. We hypothesized that mystical score on the SOCQ (Step 3) would explain significantly more variability in Openness than each of the alternate questionnaire measures (Step 2), as indicated by significant estimates of R-squared change from Step 2 to Step 3.

Finally, we compared Openness change in participants who met the criteria for having had a complete mystical experience during their high-dose session (n = 30) to participants who did not meet the criteria (n = 22). We used the "complete mystical experience" classification (60% on each subscale of the SOCQ) rather than data-driven classification (e.g., median split) for several reasons. First, median split analyses have been associated with reductions of power and effect size (MacCallum *et al.*, 2002). Second, classification based on subscale scores takes into account the breadth of mystical-type effects, which total score does not. For example, a participant could have a high total score while not endorsing many sacredness items. Finally, designating participants who met the criteria for a complete mystical experience allowed a comparison with previous studies (Griffiths *et al.*, 2008; Griffiths *et al.*, 2006; Pahnke, 1963; Richards *et al.*, 1977; Griffiths *et al.*, 2011).

Results

Changes in personality following the psilocybin session

Consistent with our hypothesis, the repeated measures ANOVA showed that Openness increased significantly from screening to post-test ($M = +2.8$, $F(1, 51) = 5.47$, $p = .023$, $\eta_p^2 = .10$). Moreover, because participants received the high dose on different sessions, it was possible to conduct a comparison analysis of changes in Openness following the first session in the subgroup of participants who did not receive a high dose of psilocybin on that session ($n = 30$ participants received inactive placebo, methylphenidate, or 5 mg/70 kg of psilocybin on their first session). There were no significant changes in Openness after the first session in this subgroup ($F(1, 29) = 0.52$, $p = .48$). Finally, with regard to changes in the other four personality factors after the high-dose session, there were no significant changes from screening to post-test in Neuroticism ($M = -0.5$; $F(1, 51) = 0.24$, $p = .62$), Extroversion ($M = +0.8$; $F(1, 51) = 0.79$, $p = .38$), Agreeableness ($M = +1.7$; $F(1, 51) = 2.31$, $p = .16$), or Conscientiousness ($M = -0.9$; $F(1, 51) = 1.22$, $p = .28$), and test-retest correlations were high across assessments (*r*s = .61 - .84). Taken together, these results indicate predominantly stable personality traits with specific increases in Openness following the high-dose session.

Relationship between session-day effects and changes in Openness

We hypothesized that individual differences in mystical experience during the psilocybin session, as measured by the SOCQ, would be related to individual differences in Openness change. There was considerable variability in mystical-type effects during the high-dose session, with nearly the full range of possible scores (range: 0.03 - 1.00) represented across the six subscales of mystical experience. Consistent with our hypothesis, mystical experience (mean score across all of the items in the six subscales) correlated significantly with increases in Openness ($r = .42$, $p = .002$; Figure 1). Importantly, mystical experience did not correlate significantly with screening levels of Openness ($r = .12$, $p = .41$) or its facets; the highest correlation was with Feelings ($r = .24$, $p = .09$).

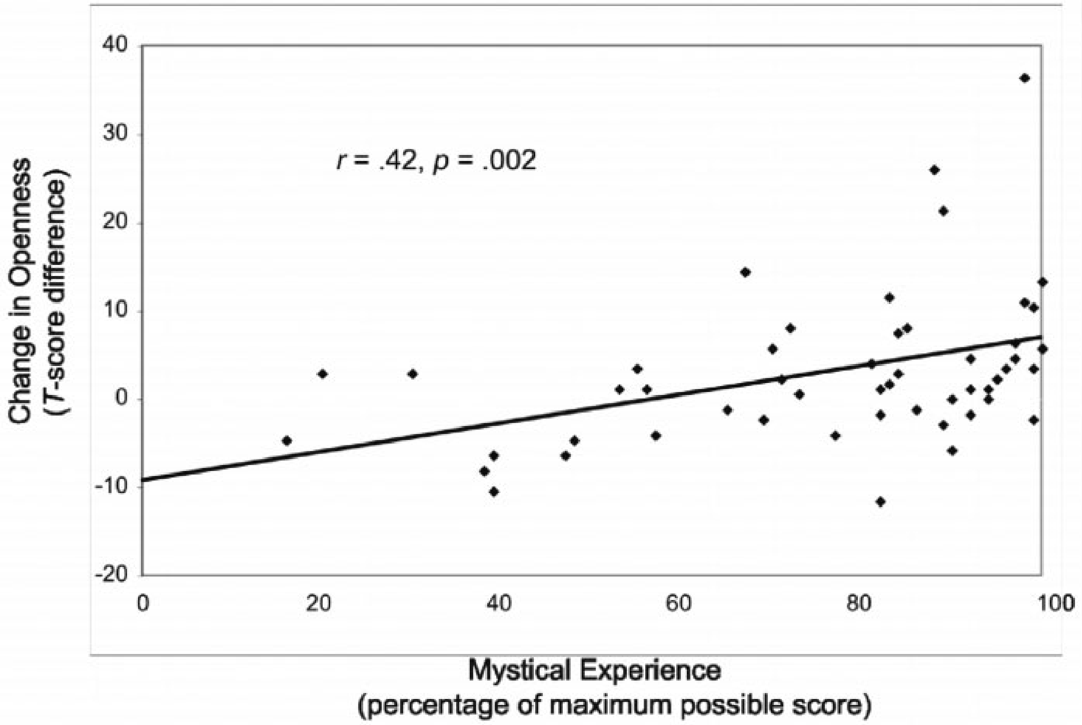

Figure 1. Change in Openness from screening to post-test as a function of mystical experience during the high-dose psilocybin session ($N = 52$). Data points show individual experimental data; a linear regression line has been fit to those data.

Changes in Openness were also correlated with scores on the Mysticism Scale ($r = .33$, $p = .017$), the OSE ($r = .44$, $p = .001$), the VUS ($r = .41$, $p = .003$), and the AIA ($r = .31$, $p = .024$). The significant relationships shown by Pearson's linear correlations were also shown by Spearman's rank order correlations between change in Openness and the SOCQ (r_s = .47, p < .001), the Mysticism Scale (r_s = .40, p = .003), the OSE (r_s = .45, p = .001), the VUS (r_s = .47, p < .001), and the AIA (r_s = .33, p = .018). However, a series of stepwise regression analyses showed that the SOCQ explained significantly more variability in Openness change than the Mysticism Scale (R-squared change = .046, p = .033), the OSE (R-squared change = .047, p = .031), the VUS (R-squared change = .042, p = .036), and the AIA (R-squared change = .12, p = .001).

Effect of mystical experience on changes in openness

We further examined the relationship between mystical experience and increases in Openness by comparing participants who met the criteria for having had a complete mystical experience during their high-dose session (n = 30) to participants who did not meet the criteria (n = 22). ANOVA revealed a significant interaction between time (screening vs. post-test) and group (complete mystical experience vs. no complete mystical experience) (F(1, 50) = 9.32, p = .004, η_p^2 = .16). Follow-up t tests confirmed that the complete mystical experience group showed significant increases in Openness from screening to post-test (M = +5.7; t(29) = 3.44, p = .002) while the other group did not (M = -1.2; t(21) = .87, p = .39) (Figure 2). Five of the six facets of Openness showed this same pattern when examined individually: The interaction between time and group was significant for Fantasy (p = .029, η_p^2 = .09), Aesthetics (p = .010, η_p^2 = .13), Feelings (p = .038, η_p^2 = .08), Ideas (p = .014, η_p^2 = .11), and Values (p = .036, η_p^2 = .09), but not Actions (p = .19). Follow-up t tests for the five facets showing significance confirmed that the complete mystical experience group increased in these facets while the other group did not (Figure 3).

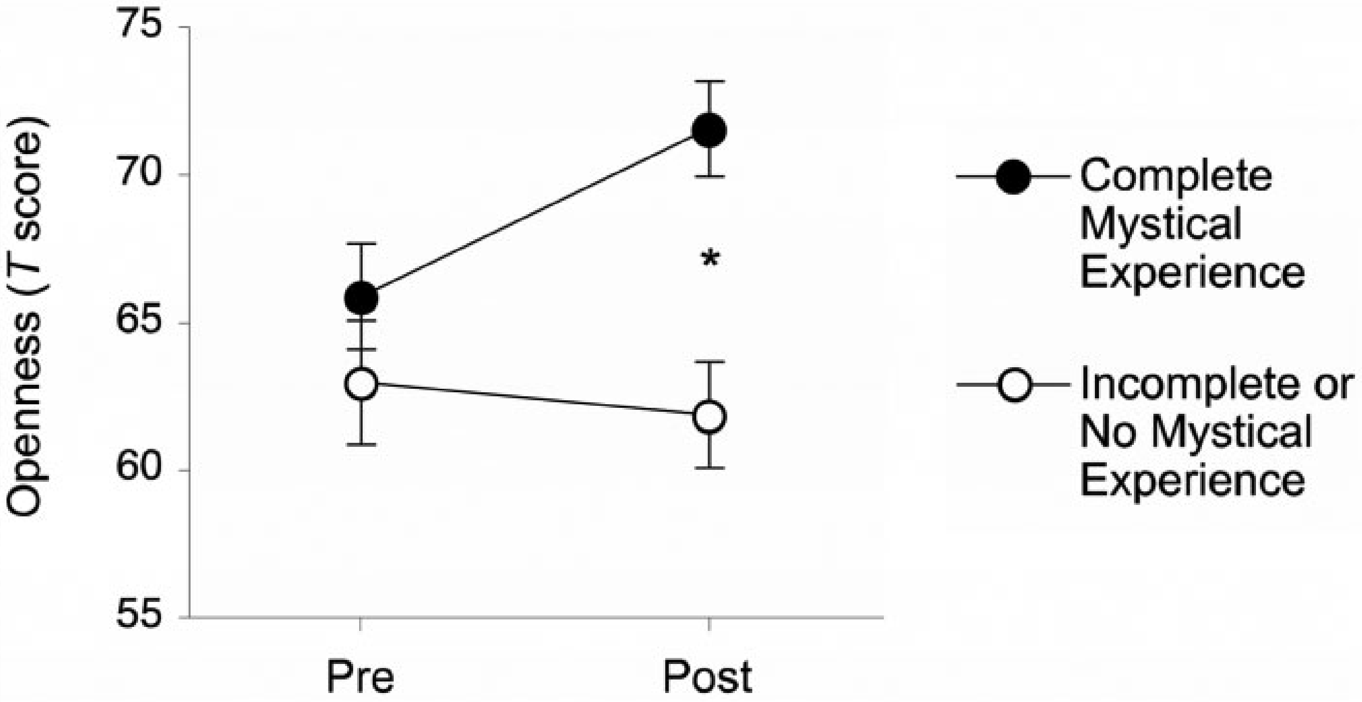

Figure 2. Changes in Openness after psilocybin in participants who did and did not have mystical experiences. Figure shows Openness T scores at screening (Pre) and post-test (Post) in participants who had a complete mystical experience (n = 30; filled symbols) and those who had an incomplete or no mystical experience (n = 22; open symbols). Data points are means; bars show ± 1 SEM; asterisk indicates a significant difference (p < .001) at the post-psilocybin assessment. Screening levels of Openness and its facets did not differ between participants who met the criteria for having had a complete mystical experience and those who did not (ps > .10).

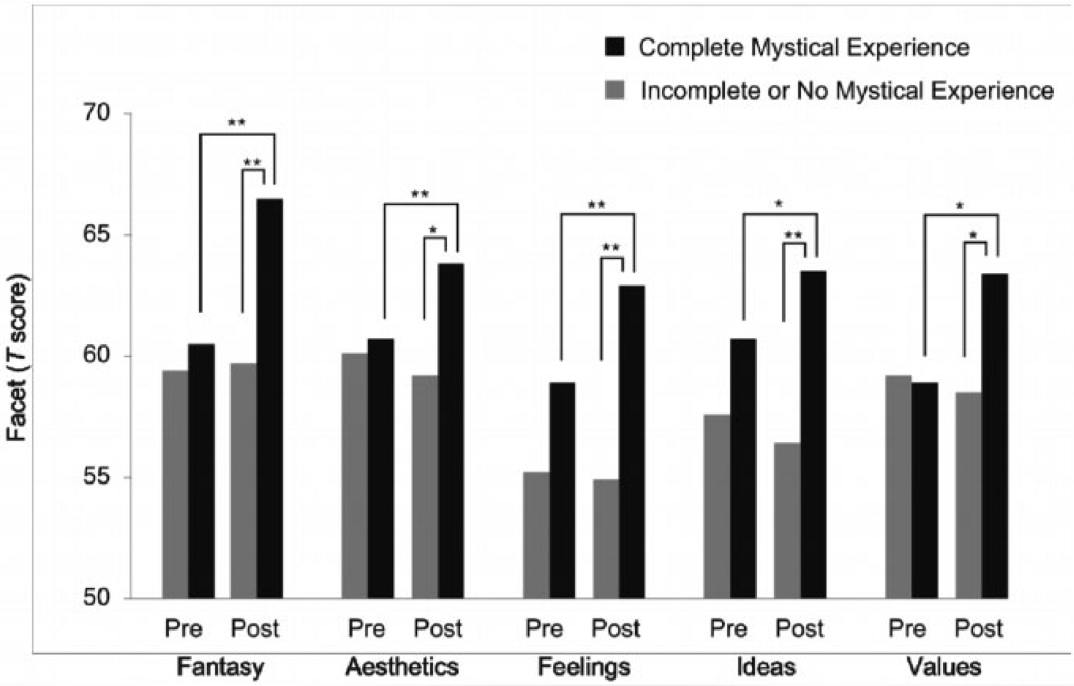

Figure 3. Changes in five facets of Openness after psilocybin in participants who did and did not have mystical experiences. Figure shows facet *T* scores (Fantasy, Aesthetics, Feelings, Ideas and Values) at screening (Pre) and post-test (Post) in participants who had complete mystical experiences (black bars) and those who did not (grey bars). Bars show means; brackets indicate statistical differences ($*p < .05$, $**p < .01$).

Follow-up

The persistence of increases in Openness was assessed at a follow-up assessment conducted more than one year after the high-dose session ($M = 16$ months). In participants who had a complete mystical experience ($n = 30$), Openness levels at follow-up decreased slightly from post-test but did not differ significantly from Openness levels at post-test ($p = .12$) and remained significantly higher than at screening ($M = +4.2$; $F(1, 29) = 4.17$, $p = .050$, $\eta_p{}^2 = .13$). In contrast, participants who did not have a complete mystical experience ($n = 21$) had nearly identical Openness levels at follow-up and screening ($M = -0.3$; $p = .86$).[1, 2]

---

[1] The overall pattern of results was similar between Study 1 and Study 2. In participants who had a complete mystical experience, there were no differences between the studies in Openness change ($p = .11$) or in Openness at screening ($p = .28$), post-test ($p = .69$) or follow-up ($p = .36$).

[2] Three participants in Study 2 met the criteria for a complete mystical experience during their 20 mg/70 kg (i.e., moderately high dose) psilocybin session but not during their 30 mg/70 kg (i.e., high dose) session. Including these participants in the "complete mystical experience" group ($n = 33$) did not change the reported results.

Discussion

We observed significant increases in Openness after a high-dose psilocybin session that were larger in magnitude than changes in personality typically observed in healthy adults over decades of life experience (Terracciano *et al.*, 2005). Moreover, in participants who met criteria for having had a complete mystical experience during their psilocybin session, Openness remained significantly higher than baseline more than one year after the session. This is the first study to demonstrate changes in personality in healthy adults after an experimentally manipulated discrete event. To our knowledge, the only other experimental (i.e., randomized) intervention reported to change healthy adults' personality involved hundreds of hours of solitary meditation over the course of three months (Sahdra *et al.*, 2011). The present findings are suggestive of lasting change in core personality traits. However, it will be important to replicate these results in larger groups of individuals with diverse baseline personality profiles.

It is informative to compare the magnitude of Openness change observed in the present study with previous findings of longitudinal personality change. During normal aging, Openness typically *decreases* linearly at a rate of approximately 1 *T*-score point per decade (see Figure 4 in Terracciano *et al*., 2005). In comparison, participants in the present study who had a complete mystical experience during their psilocybin session increased more than 4 *T*-score points from screening to follow-up. Notably, this increase is larger than increases in Openness seen in individuals treated successfully with antidepressant medication (see Figure 1 in Costa *et al*., 2005) and intensive outpatient counseling for substance abuse (see Table 1 in Piedmont, 2001).

Openness includes a relatively broad range of intercorrelated traits covering aesthetic appreciation and sensitivity, fantasy and imagination, awareness of feelings in self and others, and intellectual engagement. People with high levels of Openness are "permeable to new ideas and experiences" and "motivated to enlarge their experience into novel territory" (DeYoung *et al*., 2005). Openness is strongly associated with creativity (Silvia *et al*., 2009), and some of its facets (Ideas, Values) are correlated with general fluid intelligence and cognitive ability (DeYoung *et al*., 2005; DeYoung *et al*., 2009). Although the present study did not directly investigate the corollary benefits of increased Openness, significant increases in nearly all of the facet scores indicate the potential for improvements in aesthetic and cognitive domains.

Very few controlled studies have attempted to characterize the effects of classic hallucinogens on aesthetic and creative outcomes. One previous well-controlled study of LSD (McGlothlin *et al*., 1967) found evidence for short-term improvements on measures of artistic ability (e.g., figure drawings), aesthetic sensitivity (e.g., compatibility between participant and expert ratings of paintings), and creativity (e.g., generating alternate uses for a common object). However, McGlothin and colleagues failed to find significant improvements in creativity or aesthetic measures at a 6-month follow-up. Notably, the McGlothlin study included graduate students who were paid for participation, generally showed little interest in LSD, and received minimal preparation and support for the LSD sessions. In contrast, the present study included unpaid community volunteers who were motivated by curiosity about the effects of psilocybin and received extensive interpersonal preparation and support for the psilocybin sessions. It is likely that differences in participant motivation and preparation contributed to different long-term outcomes following hallucinogen sessions. In addition, nearly all of the participants in the present study regularly engaged in spiritual activities such as religious services, prayer, and meditation. It is possible that such individuals are particularly sensitive to the mystical-type effects of psilocybin, which were predictive of increases in Openness.

Cross-sectional methods have been used to examine differences in personality, attitudes and values between regular hallucinogen users and controls. A study in Brazil by Grob *et al*. (1996) found that individuals who used the hallucinogenic plant ayahuasca as a spiritual sacrament had lower trait levels of excitability, disorderliness and impulsivity, and higher trait levels of confidence, gregariousness and optimism compared to community members who did not use ayahuasca. Lerner & Lyvers (2006) found that individuals who used hallucinogens valued spirituality, concern for others, concern for the environment (i.e., nature), and creativity more highly than individuals who used other illicit drugs (e.g., marijuana, amphetamine, heroin). Although the findings are suggestive of personality changes that might be associated with hallucinogen exposure, it is not possible to isolate the effects of hallucinogens *per se* because of the self-selection bias that may confound results of cross-sectional studies. Longitudinal studies will be required to replicate hallucinogen-related changes in personality, attitudes, and values.

The NEO-PI is one of the most widely used measures of personality in modern psychology. However, it is useful to consider alternate methods of classifying personality. For example, the Temperament and Character Inventory (TCI) measures personality as a combination of *temperament* or automatic responses to emotional stimuli and *character* or self-aware concepts that are associated with voluntary intentions and attitudes (see review in Cloninger, 1994). The TCI scales are considered distinct from the factors in the NEO-PI. However, a factor analysis showed that TCI scales loaded on the five NEO-PI factors (McCrae *et al*., 2001). In particular, the Self-Transcendence scale of the TCI loaded on Openness, effectively representing "openness to spiritual experience" (McCrae, 2009: 154). Given the connection between mystical experience and increases in Openness observed in the present study, it is likely that Self-Transcendence might also increase following a high-dose psilocybin session.

In contrast to the numerous questionnaires available for assessing personality, very few questionnaire measures have been developed to assess mystical experiences. Despite the generally infrequent use of the SOCQ, it has been used effectively along with the more widely used and validated Mysticism Scale (Hood, 2003) to characterize hallucinogen effects (Griffiths *et al*., 2008; Griffiths *et al*., 2006; Griffiths *et al*., 2011).

Although a psychometric validation of the SOCQ has not been published, data from a study in our laboratory involving several hundred respondents indicate that the mystical items in the SOCQ have a reliable factor structure and that the factor scores differentiate self-reported mystical experiences from otherwise profound positive experiences. In the present study, the SOCQ was a better predictor of changes in Openness than other questionnaire measures of mystical effects (e.g., the Mysticism Scale) and positively experienced hallucinogen effects (e.g., the OSE). Overall, these results suggest a specific role for the SOCQ in quantifying mystical experiences and predicting personality change, although it will be necessary to continue to examine the sensitivity and validity of the SOCQ in characterizing the mystical-type effects of psilocybin and other classic hallucinogens.

The findings have important implications for the application of psilocybin and classic hallucinogens in clinical psychiatry. Recent reviews have suggested that hallucinogens could have positive effects on the outcomes of clinical disorders, particularly anxiety and mood disorders (Griffiths and Grob, 2010; Vollenweider and Kometer, 2010). Clinical work along these lines was initiated in the 1950s and suggested possible improvements after hallucinogen treatment in individuals with terminal cancer (Kast, 1967; Richards *et al.*, 1977; Grob *et al.*, 2011) and substance dependence (Mangini, 1998; Halpern, 1996; Terrill *et al.*, 1964). Although there is still much to learn about the mechanisms by which hallucinogens might produce positive changes, the increases in Openness observed in the present study indicate novel avenues of future research into the biological and psychological mechanisms of psilocybin treatment.

It will also be important in future treatment studies to examine the effects of psilocybin and mystical experience on changes in maladaptive personality traits. For example, although we did not observe decreases in mean Neuroticism (feeling tense, anxious, moody, or insecure), which was nearly 1 *SD* below normal at baseline, reductions in Neuroticism have been observed in patients undergoing treatment for depression (Costa *et al.*, 2005) and substance abuse (Piedmont, 2001). Similarly, reductions in Neuroticism might accompany reductions in anxiety and depressed mood following psilocybin treatment in patient populations (e.g., individuals with advanced-stage cancer; Grob *et al.*, 2011). In addition, although the present study focused on personality change following a single high-dose session, it is possible that multiple sessions would be associated with changes in additional domains besides Openness.

In conclusion, the present results indicate that a high dose of psilocybin administered under supportive conditions produced increases in Openness, consistent with participants' subjective claims of the long-term effects of hallucinogens. Importantly, participants who had a complete mystical experience during their high-dose session, but not others, showed enduring increases in Openness, suggesting that other mystical experiences could occasion similar change. Qualitative research has documented sudden and dramatic positive changes in attitudes, values and behaviors following spontaneous mystical or spiritual experiences (Miller, 2004; Paloutzian *et al.*, 1999). Further, correlational research has highlighted a role for spirituality in addiction recovery (Kelly *et al.*, 2011) and in coping with life-threatening illnesses such as cancer (McCoubrie and Davies, 2006), which may account for the potential efficacy of psilocybin in the aforementioned treatment of addictions and cancer distress. Future research should continue to investigate the conditions - both pharmacological and non-pharmacological - that might occasion mystical experiences, as well as describe their potential long-term consequences.

Conclusions

References

Historical documents relating to early Mormonism suggest that Joseph Smith (1805-1844) employed entheogen-infused sacraments to fulfill his promise that every Mormon convert would experience visions of God and spiritual ecstasies. Early Mormon scriptures and Smith's teachings contain descriptions consistent with using entheogenic material. Compiled descriptions of Joseph Smith's earliest visions and early Mormon convert visions reveal the internal symptomology and outward bodily manifestations consistent with using an anticholinergic entheogen. Due to embarrassing symptomology associated with these manifestations, Smith sought for psychoactives with fewer associated outward manifestations. The visionary period of early Mormonism fueled by entheogens played a significant role in the spectacular rise of this American-born religion. The death of Joseph Smith marked the end of visionary Mormonism and the failure or refusal of his successor to utilize entheogens as a part of religious worship. The implications of an entheogenic origin of Mormonism may contribute to the broader discussion of the major world religions with evidence of entheogen use at their foundation and illustrate the value of entheogens in religious experience.

Keywords: Joseph Smith, Mormonism, entheogen, psychedelic, spirituality.

Introduction

The number and quality of spiritual experiences reported by participants in early Mormonism (Welch & Carlson, 2005) far exceeded the daily background frequency reported in today's general population (Underwood, 2006, 2011). Multiple supernatural and naturalistic explanations have been suggested to account for the sheer number of early Mormon visions and ecstasies, including rational supernaturalism (Erying, 1989; Park, 2008; Widtsoe, 1915), out-of-body experiences (Bushman, 2006; Fillerup, 1996), animal magnetism or Mesmerism (Bunker & Bitton, 1975), prophetic charisma (Foster, 2005), dissociation secondary to childhood trauma (Morain, 1998), enthusiasm associated with the Second Great Awakening (Staker, 2009, pp. 19-26; Taves, 1999), apparent materialization of the sacred during trance (Taves, 2014), pious fraud (Vogel, 2004, p. vii), and automatic writing (Dunn, 2002). However, no single explanation has to date successfully accounted for the number and quality of visions in early Mormonism. Nor can these modalities explain the "on-demand" visions that were neither spontaneous nor the result of prolonged austerities. To date, Joseph Smith's and early Mormon converts' visionary experience are neither easily defined nor understood (Waterman, 1999).

Against this background, we present compelling evidence suggesting that many early Mormon visionary experiences were facilitated by entheogenic substances that resulted in mood elevation and heightened spiritual awareness among early Mormon converts. In this entheogenic working hypothesis of early Mormonism, we consider the supernatural as natural (Taves, 2014; Winkelman & Baker, 2015) and entheogens as medical therapy (Rucker, Jelen, Flynn, Frowde, & Young, 2016; Winkelman, 2001; Winkelman & Sessa, 2019). Because the two largest factions of Mormonism have opened their libraries to everyone (Spencer, 2009) and "*primary source materials are so abundant and available, far more so than for more ancient religions*" (Mason, 2015, p. 22), Mormonism may provide insight into the role entheogens played in the early success of traditional religions (see Richards, 2016; Winkelman, 2010, 2013).

Visionary experience as veridical

Converts who reported angelic visitations, ecstasies, and visions of God in 19th-century Mormonism regarded their experiences as veridical and not as imaginary constructs of the mind. The 19th-century publication, *The Essential Guide to Datura* ("Essential," n.d.), describes the subjective visionary experience of datura intoxication as "widely perceived to be real." In reviewing firsthand reports of early Mormon visionary experience, we find overlaps of these with contemporary accounts of visions facilitated by entheogenic substances, and with known symptomology associated with entheogenic use.

Defenders and critics of Mormonism may misunderstand this paper's thesis as questioning the validity of Mormonism's founding visionary experiences. Nothing could be further from the truth. All human experience and insight emerge in the chemistry of the brain, including the achievements of mathematics, science, epistemology, and even morality. To explore how brain chemistry was involved in Joseph Smith's religious experiences and those of other early Mormon believers and whether entheogens facilitated those experiences is not to question the spiritual validity and power of those experiences but to illuminate *how* such compelling experiences were accessed then and draw implications for how they may be accessed now. If the preponderance of evidence leads to the conclusion that entheogens facilitated many of Smith's visionary experiences and those of many early Mormon converts, then another oddity of the rise of Mormonism is explainable, the dramatic decline in reported visionary experience after Joseph Smith's death.

Entheogens as authentic mystical experience

Clinical research with entheogens (psychedelics) indicates that while they produce varying experiences, they also produce mystical experiences indistinguishable from those produced by non-drug means (i.e., prolonged meditation; see Griffiths, Hurwitz, Davis, Johnson, & Jesse, 2019; Griffiths, Richards, McCann, & Jesse, 2006; Richards, 2016). A double-blind study in the 1960s with students at the Harvard Divinity School (Pahnke 1963, 1966) found those sessions facilitated by psilocybin-reported experiences ranked, immediately and decades later, as among the most profound and life-shaping spiritual experiences in their lives (also see Doblin's, 1991 follow-up study). Richards (2016) reviewed this and other clinical research and examined their implications for issues in religious studies. The profound and undeniable implications of entheogens are their ability to produce genuine mystical experiences that are phenomenologically indistinguishable from the mystical experiences that result from devoted spiritual practices or which occur spontaneously. The clinical research establishes that it is pharmacology rather than personal expectation alone that enables entheogens to produce the standard core mystical features such as union with and intuitive knowledge of God, a sense of transcendence of time and space, a connection with sacredness, a sense of ineffability, and positive mood. This direct encounter with primal religious and mystical experiences provoked by entheogens has profound implications for religious studies in general (Smith, 2000, 2001), and as we will show here, for our understanding of the sacred visionary experience of early Mormonism.

Context of Mormon entheogens

Two salient characteristics of the early Mormon religion, founded by Joseph Smith (Figure 1) in 1830, were: (a) converts who were "seekers" whose "*greatest hunger was for spiritual gifts like dreams, visions, tongues, miracles, and spiritual raptures*" (Bushman, 2005, p. 147); and (b) converts who would sacrifice everything they possessed, even their own lives, and those of their family, to gather together, establish cities, and build temples to create a New Jerusalem, or Zion in America. While new religions were prevalent in the 19th-century America, the zeal with which Mormons defended their religion speaks to the charismatic power of the founding prophet, a charisma which may have leveraged entheogens for chemically induced spiritual awakening. We propose that the entheogenic context of early Mormon involved sacraments, ordinances, and endowments feeding these seekers' hunger for primary religious experience.

Discovering their yearning could be satisfied in Mormonism, seekers flocked to Joseph Smith (Figure 1), swelling Church membership from a mere 6 in 1830 to 8,000 living in Nauvoo by 1844 rivaling Chicago in population size (Hoyt, 1933, p. 50). Critical to the rise of convert numbers that the Church experienced was that between 1830 and 1836, seeker converts participating in Mormon rituals in which sacraments were ingested or anointing oils applied, had the dreams, speaking in tongues, miracles, and spiritual raptures they sought, with many enjoying visions of God and Jesus Christ (Anderson, K. R., 1996, 2012; Petersen, 1975, pp. 80-81). The experiences surrounding the dedication of the Kirtland temple in 1836 have been called the Mormon Pentecost (Olmstead, 2000), and had a similar impact on the rise of early Mormonism as the early Christian Pentecost had on the rise of Christianity; both sects faced the same charges of drug-related visions (see Acts 2:1-31, "KJV").

Sectarian observers were appalled by the strange behaviors associated with visionary sacrament meetings that Mormons had opened to the public. Of this period, the *Cleveland Harold & Gazette* reported:

> *Large [Mormon] meetings, continued for successive days, were held - earnest preachings and alarming exhortations were given ... swoons, trances, jerkings, and visions were frequent* ("The Mormons," 1839)

Figure 1. Painting of Joseph Smith, ca. 1842. Community of Christ. Public domain.

A non-Mormon medically trained observer, James J. Moss who witnessed several meetings concluded that the strange behaviors and visions were produced by drinking "medicated" sacramental wine and contemplated stealing a bottle "*to see if it were drugged or not*" (Moss, 1878). Importantly, Moss, who was a believing Campbellite and had witnessed Methodist enthusiasm during the same period, distinguished between characteristic religious enthusiasm and sensational early Mormon visionary experience. Although Joseph Smith was not present at these meetings, he attended subsequent meetings where the sacrament produced similar bodily manifestations (Bushman, 2005, pp. 156-157). In response to the multiple complaints generated by the strange behaviors of Mormon enthusiasts, Smith closed sacrament meetings to outside observers, restricted attendance to male members only, added anointings with oil, and began construction of a temple in Kirtland, Ohio. During the dedication period of the Kirtland temple in early 1836, en mass visions were once again reported by many of those who participated, with the same accusations of drugged sacramental wine (see below).

The evidence for Joseph Smith's use of entheogens explained in detail in this paper is primarily based on six straightforward phenomena reported or observed during the life of Joseph Smith.

1. Entheogens were found in every area the Smith family resided, and produce visions, and spiritual ecstasies.
2. Joseph Smith was mentored by individuals with experience in esoteric fields of knowledge.
3. Visionary experience in early Mormonism was frequently "on-demand" rather than spontaneous.
4. Joseph Smith devised a method to facilitate dramatic religious experience among his followers (Welch & Carlson, 2005).
5. There was an association between early Mormon visionary experience and participation in Mormon ordinances where bread and wine were served, and oil anointings were received.
6. Visionary experiences of the magnitude experienced during Joseph Smith's life ceased at his death.

We find the best explanation for these phenomena is Joseph Smith's personal use of entheogens and his administration of entheogens to early Mormon converts.

Entheogens as the "means"

In contrast to traditional Christianity, Smith consistently understood matter and the body to be sacred, not profane. For Joseph Smith, the physical did not impede the spiritual but was instead the *route* to the spiritual. This unique aspect of Joseph Smith's theology and prophetic practice finds expression in his doctrine of "means." In Smith's theology, divine action operates through the instrumentality of material causes, including human action and natural law. *The Book of Mormon* raises this idea to the status of a general law of divine action, asserting: "*The Lord God worketh through means*" (Smith, 1830, p. 236, emphasis added).

Joseph Smith's doctrine that God operates by "means" and that the physical is a gateway to the spiritual provides a theological rationale for using entheogenic herbs and fungi. In the view of some prominent Mormons, entheogens are not prohibited by Joseph Smith's dietary "word of wisdom" (see below). Such entheogens would be physical means God has provided for humankind to achieve spiritual ends. Smith's approach anticipated recent developments in the study of religion, particularly the role physical process plays in religious experience. In this, Smith seemed to anticipate Edward O. Wilson, professor of biology at Harvard and one of the world's leading experts on biological diversity, who concluded that "*we have come to the crucial stage in the history of biology when religion itself is subject to the explanations of the natural science*" (Fuller, 2008, p. 4).

Joseph Smith likely understood that entheogens were a trigger for religious experience, a fact vindicated when considering entheogens as simple molecules cannot create the richness of early Mormon visions and ecstasies without the human capacity for religious experience. Instead, the religious experience is a product of the body through the actions of endogenous and exogenous neurotransmitters on human cognition. Mormons regularly modify their physical chemistry to promote spiritual experience through the Mormon practice of monthly prayer and fasting, but this is an unreliable method of inducing a transcendent spiritual experience of the nature experienced at the foundation of Mormonism.

In Smith's (1835) "the Word of Wisdom," he overtly endorses the use of one mind-altering substance for spiritual ends, wine in the sacrament of communion (D&C 89:5). The revelation further teaches that "*all wholesome herbs God hath ordained for the constitution, nature, and use of man - every herb in the season thereof, and every fruit in the season thereof; all these to be used with prudence and thanksgiving*" (D&C 89:10-11). Adherence to the prohibition of addictive substances and the use herbs carries the promise of "*wisdom and great treasures of knowledge, even hidden treasures*" and protection from the "destroying angel" (D&C, 89:19-21). Herbs were a physical means to profound religious experience, experiences that rarely occur without using entheogens. As we discuss, evidence suggests that Smith gained knowledge and skill in working with herbs (D&C, 42:43; 59:17-18; 89:10-11; Haller, 2000; Heinerman, 1975), including entheogens. Joseph Smith's grandson, Frederick M. Smith, came to the same conclusion as discussed below.

Joseph Smith was also a restorationist and advocated a unique form of Native American "restoration" or "revival. From its title page onward, The *Book of Mormon* advocated a "restoration" of Native temporal and spiritual power and Smith sought alliances with Native Americans and traded objects of spiritual significance with them. If Smith learned of entheogens that bore the imprimatur of Native American shamanism, he would have been likely to seek mentors in their use, not only for himself but also for converts of his Church. Besides facilitating religious visions and spiritual ecstasies, entheogens have remarkable antidepressant properties, suggesting a motivation, possibly unconscious, for their use by the Smith family and in early Mormonism.

Wholesome herbs God hath ordained

That Joseph Smith did not consider entheogens a problem is evident from his attitudes toward herbs. Joseph Smith knew of herbs and their uses and claimed the requisite knowledge and skill to devise and prescribe herbal remedies for others (Heinerman, 1975). Joseph Smith's development into a village scryer or "seer" involved following the path set forward in several esoteric traditions of the area he grew up, and possibly from his interpretation of biblical passages indicating the ingestion of some material preceding the visions of Ezekiel and John as discussed below.

In line with other health edicts of the 19th century, in 1835, Joseph Smith delivered a revelation called "The Word of Wisdom" suggesting dietary practices and the proper and improper use of alcohol, tobacco, and other substances. However, Smith carved out an exception for plant and herb medicine in the Word of Wisdom.

> *And again, verily I say unto you, all wholesome herbs God hath ordained for the constitution, nature, and use of man. Every herb in the season thereof, and every fruit in the season thereof. All these to be used with prudence and thanksgiving* (Smith, 1835)

The first "anti-Mormon" book, *Mormonism Unvailed* [sic] by Eber D. Howe (1834), attributed the exemption carved out for "*herb[s] in the season thereof* " to Frederick G. Williams' influence on Joseph Smith (discussed below). Howe referenced Williams' herbarium on either side of his Kirtland home while disparaging his "communion with spirits from other worlds." Howe continues,

> *We are next told that every wholesome herb, God ordained for the use of man!! and we should infer that the writer or the recording angel had been inducted into the modern use of herbs, by the celebrated Doctor. F. G. Williams in Kirtland. F. G. Williams is a revised quack, well known in this vicinity, by his herbarium on either side of his house; but whether he claims protection by right of letters, patent from the General Government, or by communion with spirits from other worlds, we are not authorized to determine.* (pp. 229-230)

The Smith family exemption of entheogenic herbs as prohibited substances in the Word of Wisdom seems generational considering that Joseph Jr.'s grandson Frederick M. Smith, also a prophet to the Reorganized Church of Jesus Christ of Latter Day Saints, carved out a similar exemption for peyote as discussed below. We begin by examining the historical setting of entheogenic practices of Joseph Smith Jr. and his ancestors, mentors, and colleagues. We then summarize the evidence for the entheogens available to Joseph Smith and his mentors, followed by descriptions of early Mormon visions and ecstasies we correlate with a clinical syndrome suggestive of intoxication with visionary anticholinergic substances.

Historical setting: Ancestors, mentors, and colleagues

For Joseph Smith to fulfill his promise that every Mormon convert would have visions of God and spiritual ecstasies, he needed assistance from trusted associates who would covertly procure, process, store, and administer entheogens. Several early church leaders (including the Smiths, Cowdery, and Whitmer families in particular) were deeply invested in the study of occult practices, and herbal, plant, pharmaceutical, folk medicine /craft, and the utilization of "spirituous liquors" (Brooke, 1996; Quinn, 1998).

Salem witch trials

The Smith family involvement with the magic world view and possibly entheogenic material went back several generations. For instance, the Smiths were involved with the witch trials in 17th century Salem, Massachusetts, that may have been instigated by the psychedelic ergot fungi (*Claviceps purpurea*). Samuel Smith, Joseph Smith's great grandfather, gave testimony in April 1692 that Mary Easty threatened him after which he reported, "*I received a little blow on my shoulder, and the stone wall rattled very much*" (Smith, 1692). After the Salem trials, other generations of his ancestors resided in areas noted for beliefs and practices of folk magic and alchemy (Quinn, 1998, p. 31). European occultism also shaped the cultural milieu in which the witch trials occurred. Mormon historian B. H. Roberts noted, "*Indeed it is scarcely conceivable how one could live in New England [in the 18th-19th centuries] and not have shared such beliefs*" (Quinn, 1998, p. 29).

The hypothesis of ergotism as the culprit in the Salem witch trials of 1692 (Caporael, 1976) is based on the signs of convulsive ergotism including seeing apparitions, feeling pinpricks, pinches, burning sensations, and by symptoms of urinary obstruction. However, those afflicted had none of the constitutional symptoms or residual effects known to occur with ergot poisoning (Woolf, 2000), making poisoning by ergot-infected rye bread less likely. The manifest symptoms were attributed to potions made by Tituba, a South American Arawak Indian or Caribbean enslaved person (Albanese, 2005; Breslaw, 1996) owned by the Reverend Samuel Parris (Dannaway, Piper, & Webster, 2006). Tituba was familiar with Hoodoo religion (Martin, 2006) and plant medicines from her African heritage and could have prepared an anticholinergic such as datura (Caporael, 1976). This could have produced the symptoms ascribed to Parris' daughter, and her cousin, the first "bewitched" inhabitant of Salem, whose behaviors, resembled the anticholinergic toxidromal (Holstege & Borek, 2012) and dissociative features of Hallucinogen Persisting Perception Disorder (Martin, 2006).

Joseph Smith Sr.

The founding prophet of Mormonism, Joseph Smith Jr., was born on the December 23, 1805 into a Christian family enmeshed in folk-magic and the occult (Quinn, 1998). Joseph Smith's father, along with his other sons Alvin and Joseph Jr., engaged in the "*more esoteric components of the western New York religious-cultural situation*" (Shipps, 1987). Joseph Smith's earliest mentor was his father, who we believe would have communicated his entheogenic and magico-religious knowledge to his sons.

Ginseng extraction

Joseph Sr.'s knowledge of preparing plant extracts was recorded in 1811 when he collected and crystallized the 2018 equivalent of $57,000 worth of ginseng root (Figure 2) intended for sale in China (Smith, L. M., 1853, p. 49). Administration of ginseng root extract compares well with Modafinil, a widely prescribed pharmaceutical drug used to treat "*excessive daytime sleepiness associated with narcolepsy or shift-work*" (Neale, Camfield, Reay, Stough, & Scholey, 2013). Having crystallized and likely made use of this psychoactive themselves, the Smith's would have had no difficulty collecting, processing, and storing more potent psychoactive plants and fungi for their medicinal and magico-religious practices.

Figure 2. Ginseng found near the old Smith family farm, Sharon, Vermont (photo by Robert Beckstead).

Family magical practices

Quinn (1998) has argued that the Smiths, who lived in Vermont, New Hampshire, Upstate New York, and Northern Ohio, engaged several magico-religious practitioners of which Luman Walters (discussed below) played a significant role as mentor to both Joseph and his father (pp. 98-135). The Smith family, including Joseph Jr., possessed and employed several magic-related artifacts including astrological charts, magical parchments, a ceremonial dagger, an alchemical amulet, a silver Jupiter talisman, and a cane that all "manifest direct indebtedness" to occultists including Sibly, Scot, Agrippa, and Barrett (Quinn, 1998, p. 118). Quinn characterizes these occult books of "enormous significance" to the Smith family, especially Joseph Jr. whose cane was inscribed with symbols from The Magus conveying the message: "Jupiter-reigns over-Joseph Smith" (Ibid). Shown in Figure 3 is the silver Jupiter talisman also bearing the markings of Jupiter.

Figure 3. Joseph Smith's silver Jupiter talisman, after Barrett's *The Magus* (courtesy of Signature Books).

Joseph Smith Jr. possessed a Jupiter talisman, and a cane with a carved "serpent," a character in the Edenic allegory, and one animal believed to be "governed by both Saturn and Jupiter;" this, Quinn argues, shows that Smith relied on the works of occultists Francis Barrett and Heinrich Cornelius Agrippa (Quinn, 1998, pp. 90-91). Agrippa (1486-1535) names henbane, mandrake, and black poppy as three herbs "under the power of Jupiter" (Agrippa, 1801). According to Barrett (1801, pp. 89-92), henbane and black poppy are among the herbs used to invoke the "images of spirits" through proper suffumigations involving hemlock, henbane, black poppies, mandrake root, and other plants. Also, Joseph Smith possessed an esoteric Amulet (Quinn, 1998, p. 93) that seems to bear symbols belonging to both alchemy and masonry and representing *Psilocybe species* mushroom, which we discuss below.

The visions of Joseph Smith's parents

In 1853, Joseph Smith's mother, Lucy Mack Smith, related several family dreams in her book, *Biographical Sketches of Joseph Smith, the Prophet, and his progenitors for many Generations* and from which we learn about Joseph Smith's life growing up in the magically and religiously charged environments of sparsely populated New England and Upstate New York.

Lucy's first vision

The golden *Amanita muscaria* could be the mushroom that best fits Lucy Smith's remarkable first vision. Lucy's dream occurred c. 1802-1808, at least 3 years before her husband's two dreams in 1811 (described below) and 12 years before her son's first vision. Joseph Sr. had just informed Lucy it was best for her to "desist" attending the Methodist church because his father and older brother were very displeased. Lucy related that "*after praying for some time ... [she] fell asleep and had the following dream" in which she saw trees that "were very beautiful, they were well proportioned, and towered with majestic beauty to a great height ... I saw one of them was surrounded with a bright belt, that shone like burnished gold, but far more brilliantly*" (Smith, J., 1853, pp. 54-55).

A. muscaria occasionally forms "fairy rings" around the host tree (Figure 4), and the color of a mature *A. muscaria*, as shown in Figure 5, "*takes on a metallic sheen ranging in color from red-orange to golden or bronze*" (Heinrich, 2002, p. 14), a feature enhanced by early morning or evening light. Further, aging and drying converts ibotenic acid to the more hallucinogenic and less toxic muscimol and "*once completely dry, the golden mushroom's power is complete*" (Heinrich, 2002, p. 170). A golden *A. muscaria* surrounding its host tree may have been one of Lucy's waking memories and incorporated into this dream.

Figure 4. Ring surrounds a host tree (not shown) Shutterstock.

Figure 5. Mature, Burnished Golden *A. muscaria* (photo by Heinrich, 2002).

Lucy's dream ended with her mood lightened as she concluded that her husband would share her feelings, when "*more advanced in life, would ... rejoice therein; and unto him would be added intelligence, happiness, glory, and everlasting life*" (Smith, L. M., 1853, p. 56). Lucy's dream included a conscious memory of having seen a "burnished gold" ring probably of *A. muscaria*. If Lucy deliberately tried this entheogenic fungus, she may have done so as treatment for her lifelong depression (Groesbeck, 1988).

Joseph Smith Sr.'s first vision

Two dreams reported by Joseph Smith Sr. strongly suggest experience with entheogens whose content contains not only allisions to entheogens but also some familiarity with esoteric allegory and symbolism.

Datura dream. In what his wife described as his "first vision," Joseph Sr. found himself entirely alone, although accompanied by an "attendant spirit." In the "desolate field," before him, Joseph Sr. saw only dead, fallen timber, and heard only "deathlike silence." Querying his attendant spirit on the meaning of such desolation and dreariness, Joseph Sr. was told that ahead he would find, "*a certain log a box, the contents of which, if you eat thereof, will make you wise*." Shortly after "tasting" the contents, Joseph Sr. reports being threatened by "*all manner of beasts ... bellowing ... most terrifically.*" In the panic, Joseph Sr. escaped on the "fly," and when he returned to his natural senses, Joseph Sr. found himself "trembling." Despite the frightful experience, Joseph Sr. reported being "perfectly happy" (Smith, L. M., 1853, p. 57).

The following datura experience posted online is impressive for its robust emotional impact, the overlay of visionary material on everyday reality, and the generation of a different reality.

> *You effectively keep your rational, sober mind along with your ego while on Datura; it's rather that your sober mind is experiencing a completely different reality. Imagine normal sobriety but as you start to dream while awake. Rather than enlightenment through ego death, the nightshades offer dimensional travel to other planes of reality* (deCypher, 2008)

The frightening aspect of Smith's dream suggests a waking experience with datura fruit and his memory of the biblical warnings of death ("thou shalt surely die") associated with the "tree of knowledge of good and evil" (Genesis 2:17), coupled with his awareness of reports of fatalities associated with datura poisoning (e.g., Bigelow, 1817). Smith's guide echoes the serpent in Genesis 3:3, who advises that eating of the fruit "will make you wise." An element of Joseph Sr.'s first dream reappears in his second dream, thorns. Significantly, thorns are introduced into the world, according to Genesis 3:3, because of the ingestion of the "forbidden fruit" of the tree, perhaps symbolically referencing the thorny mature datura seedpod. What then, was the knowledge that Joseph Sr. received from his spirit guide and his dreams? According to his wife, following his two dreams, Joseph Sr. "*seemed more confirmed than ever, in the opinion that there was no order or class of religionists that knew any more concerning the Kingdom of God, than those of the world, or such as made no profession of religion whatever*" (Smith, L. M., 1853, p. 60).

A. muscaria dream. The same year as the first dream, Joseph Sr. had a second entheogen-related dream, which involved basking in ecstasy, the joy, and love associated with the Edenic tree of life. In this dream, which he related to his wife Lucy, a psychopomp leads Joseph Sr. to a tree with, "*beautiful branches spread themselves somewhat like an umbrella, and it bore a kind of fruit, in shape much like a chestnut bur, and as white as snow, or, if possible, whiter.*" As he watched, the chestnut "*shells commenced opening and shedding their particles, or the fruit which they contained, which was of dazzling whiteness*." When he partook of the fruit, he experienced something "*delicious beyond description*" and, inviting his family to eat, they "*got down upon [their] knees, and scooped [the fruit] up, eating it by double handfuls*" (Smith, L. M., 1853, p. 85).

In this dream, Joseph Sr. incorporates the spiny, thorny fruit of the chestnut, a feature of the first dream, which is similar in appearance to the fruit of datura. Instead of datura, however, the umbrella-shaped fruit scooped from the ground in the second dream evokes images of dazzling white spores dropping from the gills of an *A. muscaria* against a bright background or on a black surface.

Joseph Sr.'s esoteric Christian *A. muscaria* dream concludes with Joseph Sr. explaining to his wife, Lucy, "*I drew near and began to eat [the fruit] of it, and I found it delicious beyond description. As I was eating, I said in my heart, 'I cannot eat this alone, I must bring my wife and children, that they may partake with me.' I went and brought my family, which consisted of a wife and seven children, and we all commenced eating, and praising God for this blessing. We were exceedingly happy, insomuch that our joy could not easily be expressed*" (Smith, L. M., 1853, p. 85).

Emma Smith

Emma Hale, Joseph's wife, was gifted in using herbs. One of Emma's medicines was a healing salve that contained "jimson weed" or *Datura stramonium* (Bailey, 1952) and when the Sauk Indians visited Nauvoo in 1841, she exchanged recipes for herbal medicines with the wife of Chief Keokuk (Newell & Avery, 1994). In 1867, Emma wrote to her son, Joseph Smith III: "*I will tell you now how I make the salve. Of sweet elder bark a good large handful after it is scraped, and as much gymson [jimson] leaves and buds if they are green and tender enough to be pounded up fine*" (Bidamon, 1867; Youngreen, 2001, pp. 97, 119). Emma's grandchildren also reported her use of psychoactive medicinal beer, ginseng, and lobelia, or "Indian tobacco" (Youngreen, 2001, pp. 73, 99). Ginseng has stimulant, antidepressant, and aphrodisiac properties, while lobelia (a hallucinogen and sedative) had entheogenic uses among Native Americans (Alrashedy & Molina, 2016).

Native Americans

Smith always lived close to Native Americans and likely was influenced by shamanic activities. For instance, the Algonquin (Delaware, Fox, Ojibwa, Potawatomi, Sauk) in the Northeast and Great Plains, the Iroquois (Cayuga, Oneida, Onondaga, Seneca) in the northeast (Tooker & Sturtevant, 1979, p. xviii) and the Cherokee in the southeast (Hamel & Chiltoskey, 1975, p. 41) and their shamans resided close enough to Joseph Smith that he would have been captivated by their religious and medical practices.

In 1822 Seneca Indian Chief, Red Jacket, nephew of Chief Handsome Lake, spoke only miles from where Joseph Smith lived. Red Jacket might have sparked 17-year-old Joseph Smith's interest in Native American culture and seeking a Native American shamanic mentoring (Taylor, 2010).

Joseph Smith demonstrated his interest in Native American life at age 18 when he regaled his family with stories of ancient Indian life (Smith, L. M., 1853, p. 79), and later partially built his prophetic career on a Native platform with *The Book of Mormon*. Comparative religionist Åke V. Ström (1969) has demonstrated many parallels of Joseph Smith's teachings and practices with those of Native religions of Northeastern North America, especially that of the Algonquins. The parallels are extensive enough that Ström posits that the boy Joseph may have been heavily influenced by an Algonquin neighbor. Smith's Native American influences may have included North American entheogens, such as *D. stramonium*, *A. muscaria*, and *Psilocybe species*. The Native Americans used entheogens in medical and spiritual practices such as the Ojibway Midewiwin or Grand Medical Society. The Ojibway (Anishinaabe people) in their legend of Miskwedo described the use and effects of *A. muscaria* (Navet, 1988).

We summarize here the version told by medicine woman Keewaydinoquay Peschel (1979) where Miskwedo, the red-topped mushrooms, the spiritual children of Grandmother Cedar and Grandfather Birch. Two brothers came upon Miskwedo "*turning and revolving, buzzing and murmuring, singing a strange song of happiness under a brilliantly sunny sky*." The older brother tried to dissuade his younger brother from eating the mushroom, but defies his brother and merged with the mushroom, becoming a Miskwedo himself. Distraught, the older brother ran home to ask the medicine men what to do; and he was told to return, locate the chief and the wisest Miskwedo, and stick the quill of an eagle feather through each of their stipes to stop them turning and singing songs of happiness, then to do the same to his younger brother and carry him home. He followed the elder's instruction, and his younger brother turned back into his previous form. However, after returning home, the older brother arose in the morning "with his heart heavy with sadness and foreboding," while his younger brother "arose smiling each day, his heart filled with happiness, his lips singing merriment." The older brother became suspicious when, the younger brother urinated more frequently and took longer than before. When the older brother investigated, he found his younger brother with "arms are open wide, spread like the umbrella of a mushroom" with beautiful robes "glowing red, and tufts of white" singing with a "voice of happiness" to the "people following him." Now and forever, older brothers are unhappy in contrast to the younger brothers who "drink the Elixir of the Great Miskwedo" learning much of "the supernatural and other knowledge" by drinking "the liquid Power of the Sun."

Together, these stories transmit knowledge about *A. muscaria*, where to look for it, how to recognize it, the joys it can bestow, and the displeasure of authorities if consumed. For instance, these mushrooms are always associated with trees such as cedar and birch and have red tops with white tufts. The experience of ingesting these mushrooms includes transient ego disillusion, unity with the Divine, and mood elevations. The stories also warn of authoritarian displeasure, whom themselves refuse filling their hearts with happiness, try to suppress its use. In *The Book of Mormon*, Joseph Smith relates a similar story about Lehi's use of entheogens. Lehi comes upon a tree ladened with fruit that filled his soul "with exceeding great joy." However, others, whose dress was "exceeding fine," mocked, and pointed their fingers at those "partaking of the fruit." The scoffing caused some who ate from the tree to feel ashamed and fall "away into forbidden paths" (Smith, J., 1830, p. 20).

Midewiwin shaman are believed to possess the power of a long life, even "victory over death" through healing plants and the rituals. Such power strongly suggests that among other herbal remedies, the Midewiwin shaman utilized entheogenic material.

Delaware (Tantaquidgeon, 1972, p. 37) and Mohegan (Ibid, pp. 72, 128) peoples were familiar with datura. Native Americans living in Virginia gave a psychoactive brew called "wysoccan" to their young men during a rite of passage, causing a "derangement for 20 days," strongly suggesting it contained *D. stramonium* (Schultes, 1975, 9, 142) or *A. muscaria* (Geraty, 2015). Most North American Eastern Woodland Indian groups reported: "*datura as the base of a narcotic drink used in manhood initiation rites*" (Goodman, 1993). In 1705, Virginian Indians were reported to have been using datura in their religious ceremonies (Safford, 1922) and there was widespread use of datura in initiation ceremonies in Native North America (Jacobs, 1996). Further, sometimes, Eastern Native Americans would add "*datura and other powerful substances ... to tobacco to prepare a particularly potent smoke*" (Fuller, 2008, p. 81).

Growing up and into adulthood, Smith lived relatively near to the Algonquin areas of the Potawatomi, Ojibwa, and Delaware peoples whom all belonged to the Algonquin family. We will explore Smith's relationships with this group of peoples when we discuss his transactions with the Potawatomi in the early 1840s Nauvoo. However, it is enough to note that Smith likely noted the secretive Midewiwin medical society with its selective membership, graded training of new shamans, and their use psychoactive materials including datura and *A. muscaria.*

Esoteric Christianity

Joseph Smith was influenced at a young age by several categories of esotericism, including esoteric Christianity, spiritual alchemy, and speculative freemasonry (Owens, 1999). Significantly, some members of these esoteric schools of thought had an interest in entheogen use and encoded their knowledge in esoteric works of art.

During the 13th century, esoteric Christian artists painted Biblical themes associated with entheogenic mushrooms (Brown & Brown, 2016; also see Brown & Brown in this issue). For instance, in Figure 6 is an "Eden Panel" found in Saint Michael's Church, Germany (1240 CE) showing Adam and Eve standing, and a serpent coiled on a tree in front of a spotted *A. muscaria* mushroom cap. Also, in Figure 7, the Edenic tree also takes on the form of an *A. muscaria* in a ca. 1291 fresco found in Plaincourault Abbey, Indre, France. Figure 8 shows a painting by the Flemish artist, Petrus Christus (c. 1410-1475) portraying the child Christ laying supine on an *A. muscaria* bed looked over by Joseph, Mary, and winged angels. The relative abundance of Christian *A. muscaria* syncretic art led Antonio Escohotado (2012) to conclude, "*it seems indisputable that there is a connection between visionary mushrooms and Christianity*" (p. 73). There are reasons to think that given his esoteric background, Joseph Smith or one of his mentors had access to this art, decrypted it, and then encoded in Smith's teachings, revelations, and ordinances.

Figure 8. The Nativity, Petrus Christus, 1452 (only close up of infant Jesus is shown). Public domain.

Where then did Joseph Smith first learn of alchemy and esoteric Christianity? In his book, *Magic Mushrooms in Religion and Alchemy*, Heinrich (2002, pp. 105-153) discusses the relationship between esoteric Christianity and using *A. muscaria* as a sacramental meal. According to Heinrich, Jesus unmistakably identifies himself with an entheogenic substance, an elixir of life and bread of heaven, the *A. muscaria* mushroom shown in Figure 9. Heinrich quotes Jesus telling a woman,

> *... whosoever drinketh of the water that I shall give him shall never thirst; but the water that I shall give him shall be in him a well of water springing up into everlasting life*. (p. 120)

Figure 9. *A. muscaria* as elixir (blood of Christ) and bread (flesh of Christ) (photo by Heinrich, 2002).

The "living water," according to Heinrich, is water-soluble muscimol, the principle psychoactive in *A. muscaria*. Muscimol is excreted unchanged in the urine, which the shaman or others can consume. Supporting Heinrich's argument of entheogenic urine, we note Jesus's saying in John 7:8,

> *He that believeth on me, as the scripture hath said, out of his belly shall flow rivers of living water.*

The phrase "out of [Jesus'] belly" may describe entheogeniclaced urine. Due to physiological processes, urine after ingesting *A. muscaria* is more potent than the tea initially consumed. The entheogenic component of *A. muscaria* is water-soluble, and when extracted with water, turns the water the color of red wine. Further, the mushrooms upturned cap (Figure 9) and becomes the cup holding the elixir of life, and the mushroom itself becomes the life-giving bread. Heinrich (2002, p. 122) quotes Jesus telling he disciples:

> *I am the living bread that has come down from heaven. Anyone who eats this bread will live forever; and the bread that I shall give is my flesh ... if you do not eat [my] flesh and drink [my] blood, you will not have life in you. Anyone who does eat my flesh and drink my blood has eternal life ... for my flesh is real food and my blood is real drink ... As I, who am sent by the living Father, myself draw life from the Father, so whoever eats me will draw life from me. This is the bread come down from heaven ... anyone who eats this bread will live forever.* (p. 121)

Implied in Heinrich's discussion of these passages is his confidence that anyone using entheogens in a Christian context will experience "*many of the states described ... in mystical Christianity*" (p. 5).

Although most of Smith's revelations and teachings suggest the traditional Christian understandings of Jesus, occasionally he betrayed a different view. For instance, in 1844, Smith is reported to have said,

> *I am the only man that has ever been able to keep a whole church together since the days of Adam ... Neither Paul, John, Peter, nor Jesus ever did it ... The followers of Jesus ran away from Him; but the Latter-day Saints never ran away from me yet.* (Roberts, 1915, pp. 408-409)

In this statement, Smith seems to suggest that Jesus did not differ from him - meaning that Smith understood Jesus as shaman-like, as a human and not a God. Likewise, Jesus-like Smith healed the "lame arm" of Mrs. John Johnson (Dahl & Cannon, 1997) and raised William Hungtington from the dead (Curtis, 1892).

Spiritual alchemy

Owens (1999) argues that Joseph Smith "*certainly [learned]... about the Philosopher's Stone and alchemy's transmutational mystery*" (p. 158). Alchemy became a subject of several artists in Europe. Owens argues that Smith likely learned about alchemy from "*a physician named Luman Walter(s), who was a distant cousin of Smith's future wife and a member of the circle associated with the early treasure quests*" (p. 16) of which young Joseph was a member. Agreeing with Owens, D. Michael Quinn reasons that Walters was Smith's teenage mentor and occult advisor (1998, pp. 116-122).

In his book, *Science, Alchemy and the Great Plague of London* William S. Shelley (2017) stated "*that alchemical writings concerned chemical processes from their late antique beginning until the Renaissance. Spiritual alchemy originated, it would appear, in the early sixteenth century when Paracelsus [1493-1541] blended his medical practice of alchemy with his interest in the Hermetic-Platonic tradition of Renaissance esotericism*" (p. 4). Sometime late in the reign of Queen Elizabethan (1533-1603), alchemical texts "*seem to be exclusively spiritual, that is, that have no apparent interest in practical laboratory procedures*" (Ibid)

English alchemists such as Elisa Ashmole (1617-1692) and Robert Boyle (1627-1691), according to Shelley, "*were concerned with one or more substances, termed the red stone, the angelic stone, and otherwise, whose effects were described as spiritual*." Shelley then argues, "*these are substances that produced mystical experiences and was implicitly psychoactive*" and associates it with "*the motif of [Israelite] manna, ... the hidden manna of Revelation 2:17, ... [the] hermetic tradition, ... English alchemical literature from the Tudor period onward,*" *and in* "*the twelfth century theology of the school of Laon [northern France], afterward spreading to Cistercian, Franciscan, and other writers*" (Ibid).

Heinrich (2002) explores the connection between alchemy and entheogens, including the allegorical use of the Rebis such as the one in Figure 10 to transmit privileged knowledge of entheogenic *A. muscaria* (pp. 172-177, 184). The Rebis is a double-headed hermaphrodite linked to the prima materia, philosophers stone, an elixir of life within the allegory, *A. muscaria*. According to Lewis Spence (1920, p. 10), one of the "grand objects of alchemy" was the discovery of an elixir to ensure health and prevent death, "elixirs of life" containing herbs and medicinals that Heinrich argues are entheogens.

We now examine an amulet in Figure 11 belonging to Joseph Smith and gifted to Eliza R. Snow, his most esoteric plural wife. Figure 12 shows an inverted mushroom species (presumably *Psilocybin*) comparing favorably to the mushroom-appearing tassels dangling from both the belt worn by the Rebis in Figure 13 and the belt engraved on Joseph Smith's amulet in Figure 14. It is reasonable to propose that Figures 11 and 13 represent the same thing, *Psilocybe species* mushrooms.

Speculative Masonry

Mormon historian and former director of the Institute of Religion in Salt Lake City, Reid C. Durham documented Joseph Smith's Masonic heritage and his adoption of Masonic ritual and iconography found in the Mormon Nauvoo temple endowment (Durham, 1974). The Nauvoo Masonic Lodge, founded at the end of 1839, anticipated the spring of 1842 groundbreaking of the Nauvoo temple.

Joseph Smith's father and older brother, Joseph Sr. and Hyrum, respectively, were both Masons, and Joseph Jr. was likely familiar with Captain William Morgan, famously murdered for publishing the secrets of Masonry in 1826. After Morgan's death, his widow, Lucinda Morgan, secretly became one of Smith's 33 known plural wives in 1838 (Compton, 1997). Early Mormon leaders and successors to Joseph Smith, including Brigham Young, the leader of Mormonism's most successful schism, were deeply involved in Masonry before their conversion to Mormonism (Durham, 1974; Tanner, n.d.). There were masonic motifs, architecture, ritual, and iconography in the Nauvoo, Illinois temple. For example, on the outside architecture of the temple were the masonic sunstones, upside-down five-pointed star stones, moonstones, and a masonic compass and a square weathervane. Inside the temple, the masonic "all-searching eye" was shown on the original architect's drawing (Stack, 2002).

Joseph's mother, Lucy Smith (Anderson, 2001, p. 23; also see Joseph Smith Papers, 1844-1845) revealed how "*for a season that we stopped our labor and went trying to win the faculty of Abrac*," a secret masonic process with roots in much older traditions. Mormon scholar and historian Michael Quinn (1998) reports that the

> *Faculty of Abrac was a well-known phrase linking magic and divinity. Medieval and early modern magic manuscripts in England used "Abrac" and "Abraca" as one of the names of God in conjurations. [And that] "Abraxas [was a] Gnostic name for God that had become associated with magic*." (pp. 68-67)

In America, as in Europe, speculative masonry subsumed many mysteries in the ancient world (Casey & Gutierrez 2005, p. 222). There is evidence to suggest that these mysteries utilized entheogens including the Greek Eleusinian mysteries (Wasson, Ruck, & Hofmann, 2008, pp. 2-7), the Demeter-Persephone cult (Ibid, pp. 12-15), and the Dionysiac mystery cults (Ibid, pp. 15-18). The Roman Phrygian rites for Magna Mater (Drummond, 2013, p. 46), the Mithraic cults of Persia (Ezdejini, 2016), and the mysteries surrounding the Egyptian gods Osiris and Isis (Berlant, 2005) are all suspected of entheogen use in their rites.

According to Chris Bennett (2018), the "*imagery of the [Masonic] Lodge, was built with a set and setting that in many ways could be enhanced by the use of entheogens*" (p. 681) and the idea that some "*masonic drinks may be a remnant of early sacramental potions that contained psychoactive ingredients ... [has] been pondered for well over a century*" (p. 693). For instance, Bennett quotes from an 1835 Masonic history by John Fellows who in rehearsing the entheogens of Ancient Egyptians, Pythagoreans, and Druids, "*refers to a soporific cake of honey and medicated grain medicatis frugibus [i.e. drugged]) along with preparations of poppy and other psychoactive substances [with fellow Mason as] its target audience*" (Ibid). Bennett then notes Fellow's informing the candidate that in drinking the potion offered to him during initiation, it is a eucharist by which "*the real presence of the Saviour is manifest*" (Ibid).

In his book, *Alchemically Stoned*, the 33rd degree Mason P. D. Newman (2017) argues that features of Masonic ceremonies, architecture, and accouterments strongly suggest some Masonic lodges used entheogenic material from *Acacia* species known to contain the psychedelic dimethyltryptamine (DMT). Shannon (2008) and Nemu (2019; Editor's Note: see Nemu's article here) similarly argue for the Hebraic use of the entheogenic *Acacia* tree.

According to Mormon writer Jeffrey Bradshaw (2015), "*In the ceremonies of the Royal Arch Degree of the York rite, candidates pass through a series of veils and eventually enter into the divine presence*" (p. 162), but in the Nauvoo temple endowment, it "*is not a mere representation but is the reality of coming into a heavenly presence*" (p. 218). Mormon historian Andrew Ehat (1994) explains, "In temples, we have a staged representation of the step-by-step ascent into the presence of the Eternal while we are yet alive ... [and] "*there should have been a change in us as there certainly was with Moses when he was caught up to celestial realms and saw and heard things unlawful to utter*" (pp. 53-54, emphasis added). We argue that the "change" required to be "caught up to celestial realms" required the administration of an entheogen, a change that, like in Kirtland, would produce observable symptomatology. If this hypothesis is correct, an entheogenic endowment may have been the source of Smith's confidence that converts would in "reality" be "caught up to celestial realms." The secret that Smith needed converts to keep was the visible symptomology they would observe during the Nauvoo temple endowment.

Policy of secrecy

In an 1841 meeting, Joseph Smith explained a purpose of the lodge is to learn to keep secrets. Smith explained, "*the reason we do not have the secrets of the Lord revealed unto us is because we do not keep them*" (Roberts, 1908, p. 478) and later observed, "*The secret of Masonry is to keep a secret*" (Roberts, 1915, p. 59). What did Smith want to keep secret? Besides Smith's unusual marriage practice (Hales, 2015; Van Wagoner, 1985, 1989) and his kingdom building ambitions (Grow, Esplin, McGee, & Mahas, 2016), we argue it was to keep secret administration of an entheogen in the endowment.

Luman Walters, Occultist and eclectic physician

Mormon scholar and historian Michael Quinn (1998) reviewed the historical record about Luman Walters (1789-1860), who was an accomplished physician, preacher, and magician. Through his travels and scientific training in France, Germany, and Italy, Walters became an "eclectic" physician whose practices involved occult techniques that included the administration of medicinal herbs he processed in his well-stocked laboratory. Walters was an exceptionally qualified mentor. During Joseph Smith's teen years and early twenties, Walters utilized his occult training as an astrologer and seer for treasure companies, one of which was a "fraternity" of rodsmen, with Joseph Sr. as one of the leading members. During this period, Walters was young Joseph's "constant companion and bosom friend" and given Smith's extraordinary level of intelligence, he readily received Walters' teachings and eventually exceeded his skills as a conjurer and scryer (Cole, 1831).

Esoteric practice

Walters used a seer stone, conjuration, animal sacrifice, and likely a hallucinogen to occasion "*interview with the spirit, supposed to have the custody of [a particular] hidden treasure*" (Quinn, 1998). It was Walters who "first suggested to Joseph the idea of finding a book." Occasionally, Walters could be found reading to a receptive audience from an "old book" in a language that only he could understand and prophesied that Joseph Jr. "*was about to find ... a history of hidden treasures*" *and a* "*record of the former inhabitants of America*" (Cole, 1831; Morgan, 2014).

Joseph Jr. was chosen as a treasure seer by the same company that had hired Walters, leaving him angry and resentful (Kane, 1995). Residents believed Walters' mantle fell on the young Joseph. While acting as a seer for this company, Smith announced that he found golden plates containing a history of Amerindian ancestors, from which he subsequently "translated" *The Book of Mormon*. Smith used a seer stone to translate, and we hypothesize an entheogen; the use of the latter is suggested by reports of his frequent "intoxication" or "altered" appearance while translating. Luman Walters and Joseph reconciled because Walters was later reported to be a "disciple" of Joseph Smith in Kirtland, Ohio, suggesting Walters' direct impact on Mormon visionary experience could extend into the early Kirtland period at least (Quinn, 1998, p. 131). Walters likely received his esoteric training, including alchemical-drug expertise while studying in Europe (see below). The esoteric physician's involvement in Mormonism was confirmed by Brigham Young, one of Joseph Smith's successors (Young, 1858). Joseph Smith's alchemical-masonic amulet suggests Walter's drug-alchemical influence in Smith's early career (see below).

Medical practice

Walters' medical practice fared much better than his seership duties. He secured his medical reputation by curing a child of severe "croup" after traditional physicians had, in despair, given up. Croup was "the common term for every affection of the windpipe," stridor that produced a high-pitched crowing sound on exhalation. Porter (1826) notes that antiphlogistics (anti-inflammatories) were used by all physicians of the period, as were opium (*Papaver somniferum*) and *Atropa belladonna* and *D. stramonium*, both of which contain hallucinogenic anticholinergic alkaloids (Hartshorne, 1855).

Operating his laboratory, Walters could isolate the active anticholinergic component of the *Datura* plant as an extract or a tincture. He would know the appropriate doses to treat: respiratory diseases such as asthma, cough-variant asthma, and to relieve pain from sciatica, menstruation, and cancer (Benich & Carek, 2011). Datura was well known, and "*Indeed, so closely does it resemble belladonna, that even, in the intoxication which it produces, the same follies are committed.*" The effects of this plant are well-known in some parts of Europe, and the plant was vulgarly called "Herbe aux Sorciers" (Thomson, 1832) and was "*commonly connected with witchcraft, death, and horror*" (Folkard, 1884). Walters undoubtedly used anticholinergics such as *A. belladonna*, *D. stramonium*, and *Hyoscyamus niger* as treatments and knew of their use as visionary substances. He may have also known the antidepressant properties of anticholinergic-facilitated experience and used these medicines to treat melancholy (Drevets, Zarate, & Furey, 2013). Further suggesting that Walters prescribed psychoactives is a statement in the following report in the Geneva (NY) Times, "*In the olden days, roots, herbs and vegetables were considered highly essential as medicine for nervous disorders by* *a number of physicians. Among the early physicians to use these ingredients in his prescriptions for nervous disorders was Dr. Luman Walters, a noted physician and surgeon who practiced in the village of Gorham over a half-century ago*" (Anon., 1929).

Walters would have brought from Europe the medical and occult books from which he taught and perhaps loaned to the Smiths. Anyone with access to *The Magus*, such as Walters and the Smiths did, would read recipes describing hallucinogenic anticholinergics, or "herbs of the spirits" that could be smoked, used orally, dermally, or intravaginally. Ceremonial magicians in both Europe and America used visionary substances. Dale Pendell notes that included in John Porta's book *Natural Magick*, published in 1558, "*a number of recipes both for sleeping potions and madness potions, using stramonium (Datura), belladonna, and henbane*. Natural Magick was an immediate best-seller" (Pendell, 2005, p. 244). Weirus includes "nightshade" in his visionary formula. Although nightshade can be a generic term for members of the *Solanaceae* family, including the *Solanum* genus of food plants such as tomato, potato, and eggplant, it could also be a term for highly toxic Bittersweet (*Solanum dulcamara*), or woody nightshade, with purple and yellow flowers and red ovoid berries (Evens & Stellpflug, 2012).

Frederick G. Williams, Apothecary

One early convert to Mormonism living in Kirtland was a second-generation German immigrant named Frederick G. Williams. Born in October 1787, Williams took up the practice of medicine around 1816 after the death of his sister-in-law during childbirth. Williams gravitated towards Thomsonianism medicine and was frequently called an "herbal" or "vegetable" doctor. However, Williams (2012) did not limit his practice to herbal medicine; his skill set included setting fractured bones, suturing wounds, and treating burns, cholera, venereal disease, and delivering newborns (Williams, 2012, pp. 10, 15, 159, 162, 167). If Williams followed Samuel Thomson's (1841) *Materia Medica*, which was in its 13th edition, he would have given enemas to assist with childbirth (p. 698), and if needed, given a tea consisting of raspberry leaves and "No. 2," the later signifying the class of medicinal stimulants found in London and Edinburgh Dispensatories (p. 115). Since 1822, ergot of rye was thought "*to be the most efficacious remedy in cases of protracted labor and excessive hemorrhage*" and by 1838, was "*was available in every dispensary in London*" (Bauer, 1838, p.479).

Favoring herbs himself, Smith had great sympathy for this branch of medical practice. Soon after his induction into the religion, Smith appointed Williams to the office of Second Counselor to the Prophet, Smith's scribe, and printer for church publications. As a physician, Williams was "*universally known through this country as an eminent and skillful man*" saving Samuel Smith's wife in childbearing and reviving the newborn child (Williams, 1972). Fellow physicians living in Nauvoo used ergot in the obstetrical practices and we have no reason to believe that Williams' skills were any different.

Indian Mission

One aspect of Williams' involvement in early Mormonism was his mission journey to proselytize to the Native Americans from late 1830-1831. Joseph Smith revealed to Oliver Cowdery and three other Elders they were to commence their missionary efforts to the Lamanite, as Smith called Native Americans Indians (Smith, 1833, p. 68) and scout the location for a satellite "stake" (or congregation) to be organized in Missouri. During this journey, the missionaries met Williams, and he joined the group to meet with, and proselytize to, the Natives near modern Kansas City, Missouri, in a Native settlement known as Kaw Township. For a botanically centric physician, an opportunity to meet with the so-called "Lamanites" and intermingle knowledge of herb craft and mysticism with the people who had been using American plants for millennia would have been an exciting prospect. Dr. Williams' medical practice later reflects this newfound knowledge of "Indian medicine," as evidenced by multiple advertisements Williams published in the Quincy Whig from 1839 to 1842 (Williams, 2012, p. 169).

The overwhelming logistical constraints of supplying scores or hundreds of Mormons on multiple occasions with various plant medicines could have been satisfied by an experienced Thomsonian Botanical physician like Frederick G. Williams, with his herbarium. As evidence of their close fraternity, Joseph Smith named one of his children after Frederick G. Williams. Smith had a strong and previously unremarked tendency to draw physicians close to him and place them in positions of close confidence. Smith began his career as a seer with botanical physician Luman Walters as his mentor, and later made Frederick Williams one of his top two or three confidants. In the early 1830s, Smith ordained him his counselor in the newly organized First Presidency. In the early 1840s, he made physician Willard Richards an apostle and his private secretary. Also, around the same time, he made physician John Cook Bennett a counselor in the First Presidency and arguably his right-hand man and closest companion in the early 1840s.

Entheogenic materials

The availability of entheogenic material to the Smith family and their ability to process and utilize it are foundational to our thesis of an entheogenic early Mormonism. Sources of entheogens available to the Smith family and other herbalists interested in divination, visions, and spiritual ecstasies included *D. stramonium*, *A. muscaria variation guessowii*, *Psilocybe ovoideocystidiata*, and *C. purpurea*. Moreover, with established trade networks extending into southwestern Texas, Smith Joseph Smith potentially had access to two additional entheogens, *Lophophora williamsii* and *Incilius alvarius*.

D. stramonium and *H. niger*

Two prominent members of the *Solanaceae* plant family were available in the areas the Smith family domiciled, *D. stramonium* (Jimson weed or Jamestown weed) and *H. niger* (Black henbane). The Drug Enforcement Administration (2013) reports datura plants growing wild, as ornamentals, and in herbal gardens throughout much of the United States from the northeastern states to Texas; and the USDA plant database shows both *D. stramonium* and *H. niger* growing in extensive areas across the entire Northeastern states and other areas in the country.

Both plants contain the tropane alkaloid deliriants atropine, hyoscyamine, and scopolamine and are among the oldest medicines known to humankind (Sweta & Lakshmi, 2015); physicians used them since antiquity as effective medicinals in Eurasia (Alizadeh, Moshiri, Alizadeh, & Balali-Mood, 2014), and early post-colonial America (Ashe, 1808; Coxe, 1827, pp. 209-210). *Datura*, for example, was used for its analgesic, antispasmodic, anti-inflammatory, and antihelmintic properties (Soni, Siddiqui, Dwivedi, & Soni, 2012). Antithetically, 19th-century clinicians reported successfully treating a case of a chronic delusional state with a 10-day course of carefully prescribed *D. stramonium* (Sigmond, 1849).

Magico-religious practitioners also used hyoscyamine and scopolamine since antiquity (Muller, 1998), primarily to facilitate visions and ecstasies during divinatory and shamanic healing ceremonies, religious rituals, and witchcraft (Busia & Heckels, 2006; Keller & Kane, 1967). Anticholinergics were also used as an anesthetic by the Greek physician, Pediacus Dioscorides (c. 40 - 90 AD), and noted by the Roman encyclopedist, Aulus Celcus (c. 25 BC - c. 50 AD). In the earliest attempts at general anesthesia, wine extractions of the bark of the root of mandrake, and the seeds of opium and henbane were used to cause "dead sleep" so the patient "not apprehend the pain" of surgery (Carter, 1996).

The properties of datura were also well-known among colonials living in 18th-century Boston (Meyers, 2011, p. 40). During the 1676 rebellion by Virginia settlers, "*hungry [British] soldiers consumed the plant and then hallucinated for eleven days*" (p. 58). This same symptomology will return in 1830-1831 Kirtland.

P. ovoideocystidiata

P. ovoideocystidiata (Figure 15) mushroom ranges from Rhode Island to Kentucky and is especially common in the Ohio River valley (Guzmán, Gaines, & Ramírez-Guillén, 2007). These mushrooms are usually harvested from April to mid-June but sometimes persist into late September or early November and have a farinaceous or flour-like taste, possibly making ground-up mushroom concealable in bread.

Psilocybin-containing mushrooms have different pharmacology than *A. muscaria* and historically are a major entheogen in cultures worldwide. When ingested, psilocybin content of these mushrooms is dephosphorylated into the psychoactive compound psilocin, explaining why these fungi "*have been exploited for their psychotropic effects since prehistoric times*" (Guzmán, 2009). *Psilocybe species* mushrooms are best known for their entheogenic use in pre-Columbian Mexico, where they were used at least the last 2,000 years. *Psilocybe* mushroom use extends back to 6000 BP in Europe and to 7000 BP in Africa (Ruiz, Piper, & Ruck, 2011).

Figure 15. *P. ovoideocystidiata* (Shutterstock photo).

Amanita muscaria

A. muscaria var. *guessowii* mushrooms, such as the one shown growing near Kirtland, Ohio in Figure 16, are widely distributed in the woodlands and forests of Northeastern America, where it is recognizable by its yellow to yellow-orange cap with remnants of the universal veil forming white scales and a skirt about its stem (Ostry, Anderson, & O'Brien, 2010). It fruits in enormous quantities, often attaining dinner-plate size, and can be found growing in a circle or "fairy ring" around its host tree. The fairy ring can be striking in appearance, especially as the mushroom matures and takes on a golden color, enhanced by the early morning or evening light (Heinrich, 2002, plate 36). The cap contains ibotenic acid and muscimol, with the more hallucinogenic and less toxic muscimol content increasing as the mushroom dries.

Figure 16. *A. muscaria* var. *guessowii* found just outside Kirtland, Ohio (photo by Robert Beckstead, 2007).

A. muscaria may be the oldest entheogen known with some believing its use began after the "*last Ice Age in the northern Eurasian forest belt [and] spread north following the retreating polar ice cap, approximately 11,000 B.P.*" (Hajicek-Dobberstein, 1995. p. 100) and used as an entheogen by Siberian shaman for millennia (Lee, Dukan, & Milne, 2018). Further, Indo-European speaking groups developed "*a vocabulary pertaining to its shamanic use*" followed centuries later by the "*priests of the Vedic culture [who] sang hymns in praise of Soma the god, the sacred plant and the sacred drink pressed from the plant*" (Ibid). It appears from the 2nd to the 9th-century CE among "*Buddhist adepts ... [who] may have been ingesting this mushroom*" as an entheogen (Ibid). *A. muscaria* use appears in alchemy, Christianity, and among free and adept masons; we argue that it appears in the dreams and visions of the Joseph Smith family.

C. purpurea (ergot and mushroom)

The physicians Luman Walters, Frederic G. Williams, and John C. Bennett (see below) may have provided Joseph Smith with visionary ergot. In Figure 17, soft white sphacelia (tissue) is producing sugary or honey-tasting honeydew (Shelley, 1995). The darkly colored sclerotium in Figure 18, when mature, drops to the ground. When there is moisture, ergot on the ground germinates, forming mushroom-like fruiting bodies (stromas) with stipes and heads of various colors in Figure 19. The non-water-soluble ergopeptine alkaloids "*were the agents responsible for the recurring plagues of ergotism known throughout European history*" (Webster, Perrine, & Ruck, 2000, p. 8). The same alkaloids were used by physicians since the 16th century to stimulate uterine contraction to hasten childbirth, to stop post-partum hemorrhage, or to induce abortion (Scarborough, 1971). Use of ergot for these purposes included 1840s Nauvoo, Illinois where it was available to Mormon physicians.

Figure 17. Sweet Honeydew stage of ergot on wheat development (photo by Crop Production Magazine, 2018).

Figure 18. Ergot (*C. purpurea*) sclerotium on rye (photo by Dominique Jacquin. Shutterstock).

Figure 19. Stromata germinating on a sclerotium of *C. purpurea* (photo by KnarkKorven, 2011).

William Shelley (1995) argues that ergot use as an entheogen can be "*traced through the Greco-Roman World, through the worship of Mithra and the Hebrew Scriptures into the activities of the early Christians and from there to the 'hidden tradition' of alchemy*'" (Marshall, 1999). Water-soluble psychoactive alkaloids from *C. purpurea* (ergot) include ergonovine and methylergonovine (Webster *et al.*, 2000, p. 2). These alkaloids are believed to constitute the *kykeon* elixir of the greater Greek Eleusinian mysteries (Wasson *et al.*, 2008). Peter Webster argues that "*Greek priests could easily have harvested enough ergot [0.5 kg] from the nearby barley fields [to serve] 1000 Eleusis participants*" (Webster *et al.*, 2000, p. 8).

"*Hierophantic priests might well have discovered how to achieve partial hydrolysis of the most toxic alkaloids of C. purpurea, resulting in an extract of ergot containing a blend of psychedelic[s] ... eliminat[ing] the toxic ergopeptine alkaloids, converting them to psychoactive ergine and isoergine ... closely similar to the Aztec's ololiuqui*" (Ibid, p. 7), LSD, or psilocybin (Wasson, Kramrish, Ott, & Ruck, 1986).

The life cycle of ergot lends itself to allegory in esoteric Judeo-Christian as it does in spiritual alchemy and masonry. For instance, the manna which Moses said came from heaven tastes "like waters [made] with honey" (Exodus 16:14, "KJV"), a description consistent with ergot's honeydew stage. While undetected ergot infects bread and causes disease, water-soluble alkaloids can be added to bread, making it an entheogenic Hebrew sacrament. Consistent with entheogenic use of ergot, Moses tells the tribes of Israel that manna is "*the bread which the Lord hath given you to eat*" (Exodus 16:15), a theme echoed in the Christian era when Jesus says here is the "bread of life" (John 6:30, "KJV").

Figure 20 shows frame from the *ca*. 1200 Great Canterbury Salter, in Canterbury, England, titled "God Creates Plants" showing God with four mushroom-appearing figures below him; all five figures have uplifted hands seeming to mirror each other. This medieval salter reveals esoteric Christianity's fascination with entheogenic mushrooms. In this figure, God appears to wear an *A. muscaria* cap showing its gill side down, while the left-most figure appears to be a stylized *Psilocybe* mushroom and the far-right figure appears to represent the stromata of an ergot fungus sclerotium. The dark, purplish sclerotium in Figure 18 that has replaced a grain of rye will remain dormant for an extended time if harvested, or fall to the ground. The grounded sclerotium will eventually be moistened by rain or irrigation and produce stroma resembling tiny mushrooms in Figure 19, while Figure 21 is an enlargement of a stroma showing its yellowish-red stippled head comparable to the head of the rightmost mushroom figure in the salter frame.

Figure 20. God Creates Plants, ca. 1200. Public domain.

Figure 21. Enlarged ergot stroma (adapted from Figure 19).

A Mason and early Mormon convert, John C. Bennett, was a practicing physician and obstetrician. There is circumstantial evidence that Bennett, accused of administering "medicine" to induce abortion, was familiar with the medical uses of ergot (Hedges & Smith, 2010). Luman Walters or Frederick G. Williams likely had the education and practical training to cultivate, harvest, and prepare the psychoactive materials associated with ergot for the Kirtland temple. Bennett would have been qualified to safely prepare visionary ergot as a ceremonial entheogen in the Nauvoo temple.

L. williamsii (peyote)

During the period of Indian Removal beginning in 1830, Native Americans living east of the Mississippi River passed through Nauvoo on their way to their seasonal hunting grounds. Potawatomi delegations, also often including members of the Fox and Sauk nations, visited Joseph Smith between April 18 and August 28 of 1843 (discussed below). The purpose of these negotiations is not altogether clear to historians. However, as we will see, the negotiations probably involved Joseph Smith giving valuable and sacred property to the Potawatomi without apparent gain to Smith in return. We suggest that Joseph Smith may have negotiated with Native Americans for the delivery of peyote to Nauvoo for the Nauvoo temple endowment.

Peyote (*L. williamsii*) in Figure 22 grows along the Mexican-Texas border and has been used in Native American magico-religious ceremonies for millennia (Bruhn, De Smet, El-Seedi, & Beck, 2002). "*Indians regard the [peyote] as a panacea in medicine, a source of inspiration. Moreover, [it is] the key which opens to him all the glories of another world*" (Stewart, 1974, 1987). In aboriginal time, the peyote cult was among the Uto-Aztecan tribes (Slotkin, 1955, p. 203), and perhaps even earlier "*in the Mesoamerican and Greater Southwest cultural superareas*" (Ibid, p. 204), and among "*tribes adjacent to those of the United States: Pima, Opata, Jumano, Lagunero, and Coahuilteco*" (Ibid, pp. 206-207). The diffusion of peyotism northeastward occurred in stages beginning to the "Old Peyote Complex" of Mexico before the Spaniards arrived in the 16th century, eventually culminating in the Plains Indian Peyote Religion in the late 19th century (Slotkin, 1955, p. 28; Troike, 1962). The map in Figure 23 shows the location of the peyote beds (dark gray) and the Indian tribes (light gray) who were practicing peyotism before 1800 (Slotkin, 1955, p. 207). When Joseph Smith sent Lyman Wight to Texas to establish Mormon colonies, he would have been in contact with both the source of peyote and Native Americans expert in its use.

Figure 22. Peyote cactus (*L. williamsii*) (Shutterstock photo).

Figure 23. Tribal distribution of peyotism before 1800. Map by Allen K. Philbrick (Slotkin, 1955, p. 107)

After the Spaniards took control of what is now Mexico in 1571, peyote cults were suppressed by priests of the Catholic Inquisition, who nearly eradicated peyote rituals. An Inquisition document of 1620 outlines Catholic opposition to the ancient Amerindian religion and its peyote sacrament: " ... *peyote has been introduced into these provinces for the purposes of detecting thefts, of divining other happenings and of foretelling future events, it is an act of superstition, condemned - as opposed to the purity and integrity of our Holy Catholic faith. The fantasies suggest the intervention of the Devil, the real authority of this vice*" (Rudgley, 1993, p. 75).

Peyote cult recovery first took place among the Huichol (discussed below) and Tarahumara tribes. Peyote use among Mescaleros and Lipan Apache likely had its origin in the late 18th century with "*the Apache making one ritual complex from features selected from the totality of the Mexican and Spanish religious and ceremonial life they knew*" (Stewart, 1948, pp. 35-36). Also, Åke Hultkrantz (1997, p. 31) argued there are "*reasons to assume that Mexican tribal Peyote ritualism constituted the transition to the Plains Peyote rite, and thereby to the modern Peyote religion*" with intermediates being the Comanche, Kiowa, and Kiowa Apache. Further, there is evidence of peyote use by Lipan Apache in the 1770s. It would be naive to believe that Plains Indians shaman, medicine men, or doctors would not have been interested in peyote long before the establishment of Peyote religion.

Why would Joseph Smith be interested in peyote that requires an overland journey of 1,300 miles through Missouri, Kansas, Oklahoma, and Indian Territory before arriving in the peyote fields? We suggest that Smith heard of "aspects of peyotism" and its visionary properties as information made its way east, until in 1835, there were "*European [peyote] cactus fanciers*" (Slotkin, 1955, p. 208).

Typifying Native American's feelings about peyote, Comanchero war chief Quanah Parker once spoke of the advantage peyote offered Native American religion over those in the United States:

> "*The white man goes into his church house and talks about Jesus, but the Indian goes into his tipi and talks to Jesus*" ... *[and the Indians received]* "*their inspiration from the Great Father, while the white man [received] his through the book they have.*" (Hagan, 1995, p. 56)

Joseph Smith, who had promised converts visions of God, would have been naturally interested in the ceremonial use of peyote for Mormon rituals. Below we discuss evidence he sought to obtain peyote.

Incilius alvarius (Sonoran Desert toad)

One of the most dramatic religious experiences found in the "Tree of Life" dream accounts reported by Joseph Sr. and recorded in The Book of Mormon by Joseph Jr. may be facilitated by smoking parotid gland secretions of the Sonoran Desert toad (*I. alvarius*) shown in Figure 24 and found in the same general area as peyote (see Figures 23 and 25 below).

Figure 24. Sonoran Desert toad (*I. alvarius*) (photo by Todd Pierson, 2011). Creative Commons.

Figure 25. Distribution of *I. alvarius* in brown (Terry, 2017), *L. williamsii* in red (Hammerson & Santos-Barrera, 2004), and the proposed Mormon territory in purple (see text). The area where *L. williamsii* overlaped with the proposed Mormon territory is in blue. Distribution of *I. alvarius* and *L. williamsii* adapted from the University of Texas Libraries at Austin.

According to Lyttle, Goldstein, and Gartz (1996), "*Bufo toad (and related genera) has held a place in humanity's archaic consciousness since time immemorial. The earliest representations of Bufo toads (and toads generally) go back thousands of years. The appearance of toad-based artifacts is prehistoric were portrayed in ancient pictographs, paintings, and sculpture*" (p. 268). Secretions harvested from the parotid glands of *I. alvarius* are rich in highly entheogenic 5-MeODMT (Barsuglia *et al*. 2018; Griffiths, 2018). Evidence suggests that 5-MeO-DMT, harvested from *I. alvarius*, was an entheogen used by the Olmec, Mayan and especially the Aztec civilizations where "*Aztec icons focus in great detail on the Bufo toad's parotid glands, which contain substances that may be trance inducing*" (Lyttle *et al*., 1996, p. 269). The *I. alvarius* in Figure 24 bears a striking resemblance to pre-Columbian stone toad effigies such as the toad effigy with the Mayan Sun-God carved on its back from Northern Guatemala or Southeastern Mexico, in Figure 26, and the stone pipe toad effigy from the Ohio Hopewell Culture in Figure 27.

Figure 27. Stone toad of Hopewell culture origin (100 BC-400 AD). Ohio History Connection Archaeology Photograph Collection.

Early critics of Mormonism linked magical toads with Joseph Smith. For instance, a neighbor of the Smiths, Willard Chase, reported that in 1827, Joseph Smith's father related the following story:

> *Some years ago a spirit had appeared to Joseph, his son, in a vision, and informed him that in a certain place there was a record on plates of gold ... [and that] he must repair to the place where was deposited this manuscript ... [Joseph Smith repaired to the place] opened the box, and in it saw the book, and ... something like a toad* (Howe, 1834, p. 242)

The subsequent transformation of the toad described by Chase strongly suggests an entheogenic source for this vision.

Further, in 1830, the year Joseph Smith finished his "translation" of the "plates of gold," his occult mentor, Luman Walters reportedly possessed a stuffed toad (Quinn, 1998, p. 117), a common familiar of a conjurer (Ermacora, 2017). Walters, who traveled in Europe, would have known the toad's magical and possibly hallucinogenic properties. According to Lyttle *et al*. (1996), the more "*purely psychedelic applications of the Bufo toad had to do with the so-called toad stone, supposedly found in the head [parotid gland?] of the Bufo toad ... In 1644 [France], Boetious de Boot, in his Parfait Joallier [Perfect Jeweler], described 'the toad stone' alleged 'to exist in the toads head ... another sure talisman for obtaining perfect Earthly happiness*.'"

The twice mentioned "toad" during the production of *The Book of Mormon* suggests the remote possibility that Smith employed a toad entheogen in its writing. Further, the happiness mentioned by Boetious de Boot is a significant sequela of many early Mormon visions discussed below. For Joseph Smith to have used toad 5-MeO-DMT, it would have had to been smoked or snuffed. Further, *I. alvarius* entheogen would have had to be transported from Southwest Texas (Figure 25) along existing Indian trade routes into the American Northeast (Tanner, 1996, see map by Sanderson Associates). Peyote, found in Texas (Figure 25), retains its potency (2% mescaline) over thousands of years (Terry, Steelman, Guilderson, Dering, & Rowe, 2006), while5-MeO-DMT retains its potency over a much shorter period. Although no literature indicated how long and at what temperatures, 5-MeO-DMT remains active, if it is like is cousin, N, N-dimethyltryptamine, its salts retain their potency significantly longer than when kept in solution. Presuming this entheogen remained active between harvesting, arrival in the Midwest, and use, a stuffed toad with 5-MeO-DMT could easily supply the needs of a magician or seer for a prolonged period or a small congregation of believers for a year. Further 5-MeO-DMT would be an attractive entheogen for Joseph Smith due to its immediate and profound antidepressant properties (Davis, So, Lancelotta, Barsuglia, & Griffiths, 2018).

Had Joseph Smith known the features of entheogenic toad venom, he would have undoubtedly arranged for its procurement and transport to Nauvoo in the 1840s. Further, in 1844, Joseph Smith instructed fellow Mormons to settle the region surrounding the Rio Grande River. One follower, Lyman Wight (referenced below) went to Midwestern Texas to form the Mormon colony of Zodiac (Langford & Bandera, 2003), a site within easy traveling distance to both the peyote beds and the Sonoran Deseret Toad catchment area. Figure 25 also shows the area where the distribution of *L. williamsii* and Native American expertise in peyote sacraments and medicine overlapped with the proposed Mormon territory.

Shamanic transformation

We have discussed mentors for Joseph Smith, which we believe knew entheogens and employed them in his mentoring. Overwhelming childhood trauma suffered by Joseph Smith facilitated his formation as a shaman prophet of a successful new religion, enabling the use of entheogens to their maximum religious potential.

Unimaginable childhood trauma

Groesbeck (1990, 2004, 2005), a Jungian trained psychiatrist, has argued that the shamanic-healer archetype aptly describes Joseph Smith's personality structure. Groesbeck, who studied with a Huichol shaman, agreed with Mircea Eliade (1964) that the shaman's role and function depended on their techniques of facilitating ecstasy. According to Eliade, a shamanic healer's abilities in ecstasy or trance, to enter "*into contact with divine or semidivine beings*" (p. 84) and to "*consort with the dead with impunity*" (p. 214), generally resulted from severe trauma during early life. This shamanic complex and its archetypal pattern result from a severe illness early in life and strenuous ordeals (Groesbeck, 1975, 1989). Joseph endured such an ordeal at age 7 when stricken with life- and limb-threatening osteomyelitis secondary to typhoid fever (Adams, 2013; Morain, 1998, 2013; Wirthlin, 1981). In a horrific and prolonged ordeal, the young Joseph Smith (1833) suffered multiple exquisitely painful surgical procedures without the benefit of anesthesia or sedation. One might get a sense of what this 7-year-old boy must have endured in a revealing revelation:

> *I [God] command you [to] repent, lest I smite you … and your sufferings be sore. How sore you know not! How exquisite you know not! Yea, how hard to bear you know not!* (Smith, 1833, p. 23)

The appalling nature of young Joseph's surgeries, documented by physician LeRoy Wirthlin, is incomprehensible except to those who have experienced them (Wirthlin, 1981). William Morain, a surgeon with a Mormon background, describes how the terror of such painful surgical assaults creates dissociative injuries within a child's developing brain that become "*an integral part of the psyche that can permeate all corners of [his] mind forever*" (Morain, 2013). However, severe childhood trauma does not explain his ability to facilitate en masse visionary experience; and does not explain the anticholinergic symptoms associated with his own early visions and many early convert visions reported to have occurred between 1830 and 1831 as discussed below.

Joseph Smith Jr.'s visions

Joseph Smith Jr. had visionary experiences in his spiritual quests that display several specific features. Analysis of these accounts and the features of his experiences provide data to support the hypothesis he deliberately employed entheogenic substances.

1820: The first vision

At 14 (Smith, 1838) or 15 years of age (Smith, 1832), Joseph Smith Jr. embarked on a spiritual quest. Like the alchemical "philosophers" before him, one object of his quest was "wisdom" (Smith, 1838, 1843). Joseph Smith's later revelation "the Word of Wisdom" reflects the view that taking the proper things into one's body - avoiding addictants and using "*every herb in the season thereof*" would enable the seeker to "*find wisdom and great treasures of knowledge, even hidden treasures*" (D&C 89). Before he went into the grove in 1820 or 1821 to obtain wisdom, already three powerful precedents directed Joseph to seek wisdom through what he ate. First, he had a prototype for his quest in the story of Adam and Eve, who acquired wisdom by what they ate (Genesis 3:6, 22, "KJV"). Next, the search for wisdom had also been modeled for him by the Christian alchemists and Freemasons, who sought wisdom through the philosopher's stone, the Bible's "white stone," and by partaking of the elixir, the "hidden manna" of the Book of Revelation, which also promised that "*to him that overcometh*" the gift to "*eat of the tree of life*" (Revelation 2:7, 17, "KJV"). Also, finally, the quest for wisdom was more immediately modeled for the young Joseph by the elder Joseph, his father, who had been instructed through prophetic dreams how he could gain wisdom. Here again, the model was that one could acquire wisdom by what one *ate*.

Joseph Smith's spiritual quest is a continuation of his father's - a quest for Christ's "primitive church" for temporal and spiritual salvation, and *wisdom*. Joseph Jr. reported that a quest for "wisdom" was his motivation for going to a grove of trees where, at the age of 15, he experienced his first vision (Smith, 1839-1841, pp. 2-3). In what Lucy Mack Smith similarly called Joseph Smith Sr.'s "first vision," Joseph Sr. began a quest for wisdom and forgiveness of sins by journeying into a fallen wood. He was told, "eat," of certain edible materials found on a fallen tree, and informed, "*[this] will make you wise, and give unto you wisdom and understanding*" (Smith, L. M., 1853, p. 57). It would be remarkable if the younger Joseph's quest for "wisdom" were not informed by the visions of his father. Joseph Jr. should, therefore, have expected that to obtain wisdom, he also would need to "*eat*" something provided by God. However, where would he acquire the necessary entheogenic foods? Here again, his father's vision showed the way.

Joseph Jr. sought his visionary experience in the clearing in "early spring" (Smith, 1839-1841, p. 3), the precise time when plants would be sprouting and entheogenic mushrooms could begin to be harvested amid the dead timber. Joseph, a firm believer in providence, saw divine purposes in nature's provision of various herbs and perceived God's "hand in all things," the minute details of life (D&C 59:21; 8,9:10-11; Bradley, 2019, pp. 186-188). After seeking a physical landscape for his own "first vision" quest for wisdom that actualized the dreamscape of his father's "first vision" wisdom quest, what did Joseph intend to do when he arrived if not to *follow the commandment* given to his father in his vision, to obtain wisdom?

Against the backdrop of the biblical Adam and Eve story, the Masonic-biblical promises of "hidden manna," and the visionary commandment to his father to acquire wisdom by eating what God placed on the dead timber, Joseph Jr. was primed to perceive entheogenic plants and mushrooms at the culminating moment of his search for wisdom as a providence auguring that he needed to eat to obtain wisdom and of *what* he needed to eat to become wise.

Another potential clue to what Joseph Jr. needed to eat to gain wisdom was the biblical description of it as the "hidden manna." The original biblical manna, appearing in the story of Moses's Exodus, was described in Joseph's King James Bible ("KJV") as round edible objects found on the ground in the morning (Exodus 16:13-15). If Smith expected the "hidden manna" to take a similar form, he would have found obvious candidates all around him in the spot where he sought wisdom, growing on and hidden under the fallen trees of his father's clearing.

- Saw all kinds of improper pictures;

- [Was] seized upon by some power which entirely overcame [him];
- [Was blinded as] thick darkness gathered around [him];
- His tongue ... cleaved to [the] roof [of his mouth] so that [he] could not speak;
- He heard a noise behind [him] like someone walking towards [him];
- He sprang upon [his] feet and looked round but saw no person.
- [Was] ready to sink into despair and abandon [himself] to destruction, not to an imaginary ruin but to the power of some actual being from the unseen world [with such] marvelous power as I had never ... felt in any being (see also Harper, 2012).

Anticholinergic toxidrome

Had Joseph been taken to a local physician of the period during the initial phase of intoxication, the diagnosis of poisoning with a member of the Solanaceae family, such as Black Henbane (*H. niger*) or *D. stramonium* would have easily been made ("Communications", 1811; Copland, Darwall, & Conolly, 1826, pp. 422-423; Jonasson & Afshari, 2016; Thornton, 1811, pp. 55-61; W, 1833). Similar clinical features can also present with poisoning by the *A. muscaria* mushroom (Burkhart, 2004, p. 691; Cahill, 2003; RolstonCregler, 2017). Ibotenic acid (pantherine and agarine) and muscimol are among the active components of *A. muscaria*, substances that with powerful effects on the central nervous system. Although tropanic alkaloids are not present, the signs and symptoms of poisoning with the fly agaric are called "mycoatropinic," and they resemble those produced by *D. stramonium*, *A. belladonna*, and *H. niger* (Satora, Pach, Butryn, Hydzik, & Balicka-&Sacute;lusarczyk, 2005).

The symptoms Smith experienced related to those of the anticholinergic or mycoatropinic toxidrome were: hypertension and hyperthermia, agitated hallucinations, delirium and strange mental states, slurred speech, tremors, coma, and occasionally seizures, tachycardia and dysrhythmias, dry and flushed skin - especially the face-dilated pupils, mydriasis, and blurred vision, and dry mouth. These symptoms constitute one of five basic toxidromes (Omar, & Foxworth, 2014). Features of the anticholinergic toxidrome in Joseph's accounts of his first vision include being rendered "blind as a bat" (mydriasis, blurred vision), "mad as a hatter" (altered mental status, delusional paranoia, and hallucinations), and "dry as a bone" (dry mucous membranes), and a duration of intoxication lasting several hours or more. Paralysis associated with *D. stramonium* is also reported (Anon., 1811).

Young Joseph either understood the sublethal, visionary dose or was lucky, since coma and death may ensue in severe poisonings of *D. stramonium* (Le Garff, Delannoy, Mesli, Hédouin, & Tournel, 2016) and *A. muscaria* (Mikaszewska-Sokolewicz, *et al.*, 2016). From Eldon Watson's (1983) textural harmony of Joseph Smith's first vision, we learn that just as Joseph was anticipating ego dissolution and imminent death, a "*light appeared to ... gradually descending towards him*" until he was "surrounded by a brilliant light" creating "a peculiar sensation throughout his whole system" and causing "his mind" to be "*caught away from the natural objects with which he was surrounded; and he was enwrapped in a heavenly vision*." In the vision, Joseph's profound sense of guilt was assuaged as an angel appeared (the Lord) and assured him that his sins were forgiven. Then, "*when I came to myself again*," Joseph explained, "*I found myself lying on [my] back looking up into Heaven ... without any strength ... [but with a] mind in a state of calmness and peace, indescribable*." Joseph added, "*my Soul was filled with love and for many days. I could rejoice with great Joy, and the Lord was with me*."

Table 1 compares the relationship between Smith's symptomatology and those of the anticholinergic syndrome. Joseph Jr.'s description of his first vision is profoundly personal and unlikely to have been manufactured due to embarrassing symptoms diagnostic of anticholinergic intoxication he later attempted to hide or contextualize. Further confirming that Joseph was in a visibly physically altered condition after his initial recovery from the visionary state, he reports that upon his reentry into his family home, his mother asked him, "*What is the matter?*" (Smith, L. M., 1853, p. 133). Similar symptoms also appeared during Mormon convert visionary experience when Joseph Smith founded his Church in 1830 (referenced below).

Table 1. Joseph Smith's first vision and related anticholinergic symptoms.

Joseph Smith's symptoms	Anticholinergic syndrome
Category 1: Onset of peripheral anticholinergic syndrome	

Blind as a bat ... thick darkness gathered around [him]	Pupils to dilate widely, inhabitation of accommodation of the eyes
Dry as a bone. His tongue ... cleaved to [the] roof [of his mouth] so that [he] could not speak	Inhibition of salivary and bronchial secretion and sweating
Face and skin color changes - initially flushed, then pale	Bradycardia and decreasing blood pressure due to blocking of muscarinic M2 receptors on the postganglionic parasympathetic neurons
Category 2: Onset of central anticholinergic syndrome	
Mad as a hatter. All kinds of improper pictures	Hallucinations
Heard a noise behind [him] like someone walking towards [him]; ... sprang upon [his] feet and looked round but saw no person	Paranoia and delusion
[Was] seized upon by some power which entirely overcame [him]	Facial and body contortions, feeling bound
Was ready to sink into despair and abandon [himself] to destruction, not to an imaginary ruin	Fear associated with ego dissolution and/or actual death
Category 3: Anticholinergic visionary ecstasies and sequelae	
Surrounded by a brilliant light	Visions and ecstasies
His mind [was] caught away from the natural objects with which he was surrounded. Was enwrapped in a heavenly vision	
... an angel who had appeared (the Lord) informed him that his sins were forgiven	Hallucinations
Category 4: After effects and anticholinergic-related mood elevation	
I [lay] on [my] back looking up into Heaven ... with no strength	Post intoxication weakness and fatigue
A mind in a state of calmness and peace, indescribable	Peak experiences or afterglow phenomenon
Soul was filled with love and for many days. I could rejoice with great Joy and the Lord was with me	Sustained mood elevation
Desire to heal others	Shamanic personality (see text)

The positive symptoms associated with Joseph's vision also suggest the known antidepressant effects of scopolamine (from *D. stramonium* or Black Henbane) or possibly muscimol from *Amanita muscaria*. Scopolamine "*produces rapid and significant symptom improvement in patients with depression*" (Witkin *et al.*, 2014), similar to the afterglow phenomenon of classic entheogens (Maji&cacute;, Schmidt, & Gallinat, 2015).

A feature of Smith's "first vision" experience that cries out for explanation is its stark tangibility and experienced veridicality. He emerged from his experience of the demonic and the divine convinced of the *actuality* of the beings he had encountered: "*But exerting all my powers to call upon God to deliver me out of the power of this enemy which had seized upon me, and at the very moment when I was ready to sink into despair and abandon myself to destruction, not to an imaginary ruin but to the power of some actual being from the unseen world who had such a marvelous power as I had never before felt in any being ... I had actually seen a light and in the midst of that light I saw two personages, and they did, in reality, speak unto me*" (Smith, 1839-1841, p. 4). Smith either found himself bound by an "actual being" and then "actually saw" a light, or there were neurophysiological changes in his brain and body that facilitated their perception. Even if Smith is understood to have encountered external spiritual forces, one would have to explain what physiological changes facilitated his ability to physically engage with entities that cannot usually be seen or felt. Entheogenic *D. stramonium* explains how Joseph Smith perceived his engagement with spiritual forces as an actual physical encounter.

A high dose of psilocybin would have provided the mind-opening, cosmological, transformative, and disintegrating/ reintegrating aspects of the experience, while *D. stramonium* would have given the experience of another reality, initially in the grips of a terrifyingly, physically *real* evil being. Unbeknownst to Joseph Smith, as for the mythical Adam and Eve, eating the "forbidden fruit" entailed an experience of evil in tangible form (Satan/the serpent) to obtain wisdom - that is to experience the "deepest abyss" besides "commune with God" (Smith, 1977, p. 137). Smith also acted the part of an alchemist transmuting or "transfiguring" his physical state to enable himself to find wisdom through the visionary experience of both good and evil, Satan and God.

It is also possible that Joseph Smith used *P. ovoideocystidiata* or another species of psilocybin-containing mushroom, although this is less likely than an anticholinergic entheogen based solely on the symptomology. We mention the possibility of *P. ovoideocystidiata* use here because this mushroom can be found from Rhode Island to Kentucky and is especially prevalent in the Ohio River Valley (Allen, Gartz, Molter, & Sihanonth, 2009; Guzmán *et al.*, 2007), where it grows on wood debris, especially along rivers, streams, and wet valley areas such as the Sacred Grove. The Sacred Grove hosts a great variety of fungi, besides *A. muscaria* due to it residing in a small valley of seasonally wet and cooler terrain. On two visits to the Sacred Grove before the conception of an entheogenic origin of Mormonism, one author (RB) found abundant mushrooms of several varieties, including one in Figure 28. The photographed mushroom in the sacred grove appears suspiciously like a *Psilocybe species* mushroom in Figure 29; unfortunately, no field-testing for the typical blue reaction to pressure was conducted.

Figure 28. Mushroom found in Sacred Grove (photo by Robert Beckstead).

Figure 29. *Psilocybe* species (Shutterstock photo).

Entheogenic replication of Smith's first vision

Many examples of entheogenic experiences are reported in peer-reviewed literature and on the internet that bear a striking similarity to those of Joseph Smith. For example, religious historian Huston Smith initiation into "ultimate reality" was occasioned by a psilocybin-containing mushroom. Huston reports:

> *What the day accomplished, ... was to enable me for the first time to experience the respective levels of the Chain [of Being], all the way to its top. The dominant effects of the experience were two: awe (which I had known conceptually as the distinctive religious emotion but had never before experienced so intensely) and certainty. There was no doubting that the Reality I experienced was ultimate. That conviction has remained. (2001, p. 126)*

In the same year (1961), Huston ingested peyote cactus and reported: "*I noted mounting tension in my body that turned into tremors in my legs ... I [began] experiencing ... the clear, unbroken Light. I was now seeing ... with the force of the sun, in comparison with which everyday experience reveals only flickering shadows in a dim cavern ... [I saw] worlds within worlds*" (2000, p. 11). Smith concluded that using entheogenic substances can occasion an experience with a form indistinguishable from those of the experiences of religious mystics.

Heinrich (2002, pp. 201-203) ingested *A. muscaria* as the entheogenic facilitator and reported:

> - I felt like I weighed thousands of pounds and could no longer sit up.
> - [In] a great darkness and a great silence, the heavens opened above my head.
> - The bliss I had experienced prior to this new revelation now paled to insignificance in an immensity of light that was also the purest love.
> - The absolute profundity of the experience cannot be denied, neither can be adequately expressed, though one is moved to try.

Huston's and Heinrich's entheogenic reports reveal the core features of Smith's earlier vision: an experience of physical heaviness, visual darkness, an awe-inspiring light from above, a voice out of heaven, experience with the unfathomable Godhead and feelings of unspeakable joy.

Joseph Smith's actual first vision

His "actual first vision" and a vision of a divining instrument, a "seer stone," initiated Joseph Smith's career as a visionary scryer. Mormon historians connected this seer stone vision, in which Smith saw "*a small stone ... which] became luminous, and dazzled his eyes, and after a short time it became as intense as the mid-day sun*," with his theophanic "first vision," linking the visions conceptually and placing them in roughly the same time frame (Bradley, 2010; Purple, 1877).

Smith's understanding of his white seer stone as the white stone of Revelation 2:17 also connects it with the white stone of Hiram Abiff and, therefore, the "hidden manna" mentioned in the Masonic degrees and thought to have been administered in the more esoteric versions of those degrees.

It was from underneath of the acacia sprig, believed to be an entheogenic symbol in masonic lore, that Hiram Abiff's remains and "jewel" were reportedly excavated (Bernard, 1829). Conflating "jewel" and "white stone," Smith may have conceived of Hiram Abiff's body and "white stone" being recovered together from under the tree. The acacia marking the burial site of Hiram Abiff's body and "jewel" is understood in freemasonry as a "tree of life" (referenced below).

Joseph Smith reported excavating under a tree to find his white stone, recalling the excavation of Hiram's white stone under the acacia tree. After recovering this stone, Joseph Smith placed it in the darkness of his hat, looked into it, and discovered that he had acquired "*one of the attributes of Deity, an All-Seeing Eye*" (Bradley, 2010; Purple, 1877) reflecting another probable occasion on which he ate from an entheogenic plant. Joseph Smith, eating from such "tree of life" anticipated *The Book of Mormon*'s descriptions of an entheogenic "tree of life," discussed below.

1823 Indian visions

Joseph Smith's next vision in 1823 is notable for the post-vision weakness and its ancestral Amerindian content. The many ancestral Amerindian tumuli found and excavated in New York and Ohio undoubtedly fascinated the young Joseph, as did the widely held belief that Amerindians were the remnants of Lost Tribes of Israel. However, as he had 3 years previously, Joseph's vision was preceded by fervently asking forgiveness of his sins. When the vision opened, a brilliant light appeared; and in the light, Joseph claimed that he saw an angel, identified as an ancestral Amerindian, with whom he spent the entire night. "*I discovered a light appearing ... until the room was lighter than at noonday, when immediately a personage appeared at my bedside, standing in the air ... his whole person was glorious beyond description, and his countenance truly like lightning. The room was exceedingly light ... When I first looked upon him, I was afraid. [And he] said there was a book deposited, written upon gold plates, giving an account of the former inhabitants of this continent*" (Smith, 1830, front piece). Following these visions, Joseph arose to work on the family farm but on meeting his father in the field, "found [his] strength so exhausted as to render [him] entirely unable" to labor.

Psychedelics in *The Book of Mormon*

Several lines of evidence in *The Book of Mormon* suggest Joseph Smith's awareness of psychedelics and their effects. *The Book of Mormon* functioned as sacred scripture and acted as a psychopomp for early Mormon converts seeking direct and personal experience with God under the influence of entheogenic material. Consistent with this view, Mormon Jungian psychiatrist Groesbeck (2004) argues for *The Book of Mormon* as "symbolic history." We suggest that passages in *The Book of Mormon* and other early Mormon sacred writings guide spiritual experiences as outlined by Leary, Metzner, and Alpert (1964) in discussing the Tibetan Book of the Dead - to establish a setting for predisposing early Mormon converts to direct and personal experience with God through spiritual ecstasies. Another aspect of the set and setting of early Mormon visionary experience is Joseph Smith himself - as the archetypal shaman. Leary *et al*. (1964) emphasize the need for "*a trusted person ... to remind and refresh the memory of the voyager during the experience*." Smith was that trusted person.

Herbs, although not frequently mentioned in *The Book of Mormon*, are highly endorsed as medicines explicitly and entheogenic substances implicitly. For instance, *The Book of Mormon* speaks of the "*excellent qualities of the many plants and roots which God had prepared to remove the cause of diseases*" (Smith, 1830, p. 353). We argue here that Smith, in *The Book of Mormon*, intended to reference not only the treatment of bodily diseases but also maladies of the soul. While traditional herbs may be useful for treating ailments relating to the body, it is the entheogenic herbs that lift the mood and relieve despair, as demonstrated after partaking of unusual fruit described in Joseph Sr.'s entheogenic dream discussed above and in *The Book of Mormon* tree of life allegory discussed below. Also, in *The Book of Mormon*, Smith associates the use of herbs with symptomatology such as

- death-like experience lasting days rather than hours,
- symptoms resulting in sensations of tongue swelling,
- sensations of motions,
- taste of light,
- enlightenment, and
- mood elevation

These symptoms, in our view, demonstrate that Smith encoded his entheogenic knowledge encoded in *The Book of Mormon*.

Death and rebirth symbology (ego death)

Mormon historian Don Bradley (2019) interprets that Joseph Smith's first vision is an initiation or endowment transforming an unaccomplished young man from an improvised family into religious royalty as a seer and prophet. We argued here that Smith's first vision, facilitated by an entheogen, corresponds to similar royal entheogen-infused death and rebirth initiation rituals. Knight and Lomas (1996) explain:

> *The new king would have undergone 'death' by means of a potion administered by him to the high priest in the gathering of the inner group of the holders of the royal secrets. This drug would have been a hallucinogenic that slowly induced a catatonic state, leaving the new king, as inert as a corpse.* (p. 145)

An entheogenic initiation of this nature would change the thoughts and feelings previously held by the new king. Two *Book of Mormon* narratives reflect entheogen-infused royal initiation rites discussed by Knight and Lomas. In the first narrative, after being chastised for unrighteousness,

> *[The King] fell unto the earth, as if he were dead ... for the space of two days ... under the power of God ... and the light which did light up his mind ... had infused such joy into his soul (276-7) [and similarly, the Queen then arose and] ... cried ... O blessed Jesus ... [clasping] her hands, being filled with joy.* (pp. 278-279)

In the second narrative, the son of a Prophet King unprepared to succeed him on the throne is reprimanded by his father. In this account, the son reported:

> *I fell to the earth; and it was for the space of three days and three nights, that I could not open my mouth; neither had I the use of my limbs ... I [thought] that I could ... become extinct both soul and body ... [after three days and three nights] I cried within my heart, O Jesus, thou Son of God, have mercy on me, ... and when I thought this, ... I was harrowed up by the memory of my sins no more. And O, what joy, and what marvelous light I did behold; yea, my soul was filled with joy as exceeding as was my pain.* (pp. 324-325)

These remarkable narratives in *The Book of Mormon* parallel the first-vision accounts given by Joseph Smith supporting the thesis that his first vision was an entheogen-infused initiation. In his first vision,

1. Smith felt profound guilt and shame associated with his sin (Smith, J., 1832, p. 6),
2. He was in mortal fear of "sudden destruction" (Smith, J., 1839-1841, p. 3),
3. When Smith came to himself, he "*was sprawling on [his] back and it was some time before [his] strength returned*" (Smith, J., 1842, p. 748).
4. Afterward, he had feelings of "*calmness and peace, indescribable*" (Pratt, 1840, p. 7).

We suggest that more than coincidence, Joseph Smith's first vision, *The Book of Mormon* death and rebirth accounts parallel Knight and Lomas' entheogen-infused royal initiation rite. It seems reasonable to conclude that Smith's experience and *The Book of Mormon* accounts were related to esotericism and entheogens.

Synesthesia

One feature of visionary experiences reported in *The Book of Mormon*, synesthesia (the stimulation of one sense modality provoking sensation in another) strongly suggests the effect of an ingested entheogen. In *The Book of Mormon*, Joseph informs the convert that after ingesting the seed of the fruit of the tree, they should expect it to feel "swelling" within the chest closely followed by "swelling motions." After the onset of the swelling motions, Smith informed converts to expect the appearance of light that "enlightens the understanding" so the "mind doth begin to expand," i.e., experiences the desired psychedelic properties of the seed. This mind expansion is accompanied, according to Smith, by the taste of light suggesting the phenomena of psychedelic associated synesthesia: "*when you feel these swelling motions ... it beginneth to be delicious ... ye have tasted this light*" (Smith, 1830, pp. 315-316).

Two examples will be most relevant here: Lehi's dream of the tree of life and Alma's parable of a seed that grows into a tree of life. Joseph Jr. inserts into *The Book of Mormon* a vision of an Edenic tree its fruit, and upon ingesting it, the profound experience of the love of God - nearly identical to his father's Edenic vision in 1811 (Smith, 1830, pp. 18-21). Another probable reference to synesthetic bodily symptoms in the text of *The Book of Mormon* appears in a parable by the prophet Alma comparing God's word to a seed. The parable describes the cultivation of a plant from seed, ultimately to a full-grown tree revealed to be, like Lehi's, "a tree of life" bearing fruit.

> *Now, we will compare the word unto a seed. Now, if ye give place, that a seed may be planted in your heart, behold, if it be a true seed, or a good seed, if ye do not cast it out by your unbelief, that ye will resist the Spirit of the Lord, behold, it will begin to swell within your breasts; and when you feel these swelling motions, ye will begin to say within yourselves - It must needs be that this is a good seed, or that the word is good, for it beginneth to enlarge my soul; yea, it beginneth to enlighten my understanding, yea, it beginneth to be delicious to me.* (Smith, 1830, p. 315)

The effects of cultivating this seed expand the mind, enlarge the soul, stimulate the taste of light, and produce inexpressible joy and happiness. In these passages, Joseph Smith encapsulated the very meaning of the current meanings of "psychedelic" and "entheogen." More importantly, at least as far as Joseph Smith is concerned, the reader of *The Book of Mormon* is invited in this passage to experience the same psychedelic or entheogenic enlightenment, synesthesia, and transformation as he had.

Mood elevation

Descriptions of the visionary dreams of Joseph Smith's father, and his first vision, his Indian visions, and early Mormon visions in Kirtland Ohio (discussed below) manifest mood-elevating properties. The mood-elevating effects of entheogens are well established: eventually, they will be one modality of managing treatment-resistant depression (see articles in Winkelman & Sessa, 2019). The antidepressant effects of psychedelic experience suggest motivational salience for entheogen use throughout history and specifically in the Smith family to facilitate visionary experience and as antidepressants. La Barre (1947) observed that Native American peyote use in religious confessionals provided a primitive form of psychotherapy. Similarly, the mood-elevating sequelae of Joseph Smith's use of entheogens in early Mormon rituals and confessionals was practical psychotherapy for early Mormons; and likely unconscious salience for conversion to Mormonism and convert resilience during the hardships of Mormon diasporas.

Entheogenic ordinances

In early Mormonism, converts anticipated visions and direct face-to-face communication with God, but only in the context of Church ordinances administered by Joseph Smith. In 1832, Joseph Smith explained:

> *And this greater priesthood administereth the gospel and holdeth the key of the mysteries of the kingdom, even the key of the knowledge of God. - Therefore, in the ordinances thereof, the power of godliness is manifest; and without the ordinance thereof, and the authority of the priesthood, the power of godliness is not manifest unto men in the flesh; for without this no man can see the face of God, even the Father, and live.* (Smith, 1833, Section 4)

Importantly, visions and ecstasies in early Mormonism are associated with ordinances involving the serving of bread and wine sacraments, and anointings of bodies with anointings; while the expected visionary Nauvoo temple endowment also features oil anointings but adds plucking fruit from tree branches. In June, Joseph Smith (1839, pp. 17-18) told trusted leaders:

> *God hath not revealed anything to Joseph, but what He will make known unto ... the least Saint ... for the day must come when no man need say to his neighbor, 'Know ye the Lord; for all shall know ... [he] will have the personage of Jesus Christ to attend him ... and the visions of the heavens will be opened unto him, and the Lord will teach him face to face.*

It is likely that models of Biblical visions, and esoteric-minded mentors guided Joseph Smith to ingest something crucial to his own visionary experience.

> - Genesis 2:17 pointed to the need to eat the fruit of any tree in the garden to retain peace, happiness, and tranquility (possibly *A. muscaria*), but not the fruit of the tree of knowledge (possibly datura).
> - Moses instructed Israel to eat manna that tasted like a water made with honey (Exodus 16:31).
> - Ezekiel (3:1-3) eats a scroll that was as sweet as honey in Ezekiel 3:1, the consumption of a

> scroll or book tasted "*as honey for sweetness*." - John, in association with his vision in Revelations 10:10, eats an entheogen that tastes sweet but in "*belly [it] was bitter*."
> - Jesus said, "*To him who conquers I will give some of the hidden manna, and I will give him a white stone*" (Revelation 2:17, see also 10:9).

In each of these cases, the ingestion of some substance tasting bitter, sweet, or forbidden was transformative. Gastrointestinal upset is a feature of ergot alkaloids (Schiff, 2006), *Psilocybe species*, and *A. muscaria* mushroom ingestion (Beug, Shaw, & Cochran, 2006). Also, Smith expounded on the Revelation of St. John, explaining that "*the little book which was eaten by John, as mentioned in the 10th chapter of Revelation*" is understood to be "*an ordinance*." In this statement, Joseph Smith informs converts that visions are associated with consuming a substance or the application of anointing oil during Mormon ordinance work.

Early convert visions

As a budding prophet, Joseph Smith's altered appearance was readily apparent to observers (see Sally Heller above), but with experience, his demeanor during visions did not so readily betray an altered state.

Early Mormon converts, as novice prophets themselves, would experience altered states similar to those reported by Joseph Smith in his early visions.

For instance, in an 1832 shared experience Joseph Smith and his first counselor, Sidney Rigdon alternately related what they saw in vision while others wrote the revelation down. As was the customary order of the priesthood at that time, Smith and Rigdon likely partook of the sacrament at the beginning of this meeting. After this vision, Sidney appeared pale and exhausted.

As a budding prophet, Joseph Smith's altered appearance was readily apparent to observers (see Sally Heller above), but with experience, his demeanor during visions did not so readily betray an altered state. Early Mormon converts, as novice prophets themselves, would experience altered states similar to those reported by Joseph Smith. For instance, in an 1832 joint vision reported orally by both Joseph Smith and Sidney Rigdon each taking turns and witnessed by several others, likely after partaking of the sacrament that was the custom, Sidney appeared exhausted. An observer reported: "*Joseph sat firmly and calmly all the time in the midst of a magnificent glory, but Sidney sat limp and pale, apparently as limber as a rag, observing which, Joseph remarked, smilingly, 'Sidney is not used to it as I am'*" (Dibble, 1892; for a description of this vision, see Smith, 1835, pp. 225-231; Woodward, 2012).

Joseph Smith's and Sidney Rigdon's account of this vision was added to the Latter-day Saint canon as Doctrine and Covenants, currently Section 76. This vision entailed a physical change, elsewhere called "transfiguration," a change that converts would experience in their own bodies in connection with priesthood ordinances, if they desired to see God and Heaven. According to Smith, such a transformation of the body was needed so that "*while in the flesh, they may be able to bear his presence in the world of glory*" (D&C 76:117-118; Moses 1:11, 31). Smith taught that Mormon ordinances and "transfiguration" were prerequisite to visionary experience. Partaking of an entheogen would account for the physical symptoms experienced by Sidney Rigdon and other early Mormon converts and also account for the "transfiguration" phenomenon. Early Mormons were led to understand that distressing bodily symptoms following sacraments and anointing were nothing to fear but instead to eagerly anticipate.

Early Mormon converts prepared for entheogenic Church ordinances in several ways. Many of the most ardent early Mormon converts joined Mormonism after hearing of convert visions and after reading *The Book of Mormon*, which itself has multiple allusions to entheogenic experience. These allusions, we argue, prepared converts to experience similar entheogenic interactions with Heaven and divine beings. Among the significant exhortations Joseph Smith gave on this topic did not have so much to do with personal worthiness as it did by a willingness to participate in the ordinances and loyalty to the Church and himself. If a member remained loyal, Smith in effect guaranteed their personal and immediate success in accessing Heaven and angels and receiving revelation themselves.

Smith's promise that converts would see God and experience visions, dreams, and ecstasies would occur in receiving sacraments and endowments. The settings where sacraments were received were initially nature-based, followed by private homes; and later shifted to specially constructed temples incorporating mystical symbols, including symbols utilizing esoteric and masonic imagery. For instance, labyrinths, gonfalons, spirals, and squares within squares adorned the Kirtland temple. Even more mysterious, unquestionably alchemical-masonic symbols decorated the Nauvoo temple. Further, Joseph Smith himself was the trusted guide for ceremonies, prayers, and singing; and when necessary, Smith managed problematic entheogenic experiences. By following this entheogenic protocol, Joseph Smith facilitated an unprecedented number of "on demand" religious visions and ecstasies.

Three witness' visions

The type and quality of visionary experience among Mormon converts was similar to that experienced by Joseph Smith, including the replication of the troublesome symptomology reported by Smith. Converts receiving visions containing doctrine and commandments that contradicted that of Joseph Smith, however, were tightly controlled by him and non-binding on the Church (Smith, 1835, p. 181).

In July 1829, shortly after Joseph Smith completed his work on the text of *The Book of Mormon*, Oliver Cowdery, David Whitmer, and Martin Harris accompanied Joseph Smith in prayer and Cowdery, Whitmer, and Smith, and then separately Harris and Smith, experienced visions of an angel descending from Heaven and showing the golden plates and other artifacts associated with *The Book of Mormon*, a testimony they never recanted even when ridiculed.

However, considerable controversy raged in the 19th century and today about whether the witnesses saw the plates in a physical, sensory way (with "natural eyes") or in an altered, visionary state (with "spiritual eyes"). One witness, Martin Harris, equivocated on whether the experience was "natural" or "spiritual." Further light was shed on the experience by another witness, David Whitmer: "*I have been asked if we saw those things with our natural eyes. Of course, they were our natural eyes. There is no doubt that our eyes were prepared for the sight, but they were our natural eyes nevertheless*" (Vogel, 2003). Of particular interest to this discussion is David Whitmer's statement that: "*our eyes were prepared for the sight*." In 3 Nephi 28 found in *The Book of Mormon*, Joseph Smith's reveals that the physical body must change, or "transfigure" to see spiritual things or else they would die (Moses 1; 3 Nephi 28). From Whitmer's testimony, it appears that *The Book of Mormon* witnesses were informed by Joseph Smith either directly or in the form of *The Book of Mormon* passages that symptomology precedes visionary experience.

The Three Witnesses and Mormon converts alike were aware of the biblical precedent involving Adam and Eve eating the "forbidden fruit." Another precedent involved the practice of receiving communion, in which ordinary food and drink received an Apostolic blessing leading to those present at the visionary Christian Pentecost to appear intoxicated. The telling of Joseph Smith Sr's. entheogenic dreams and the entheogenic accounts in *The Book of Mormon* would also have provided yet another precedent. All of these precedents, and others discussed in this paper, placed in the immediate backdrop of their vision, provided "emotional immunization" from fear and embarrassment secondary to the troublesome entheogen-related physical and emotional symptomology preceding their visionary and ecstatic experience.

1830: New York visions

Joseph Smith promised converts visions, but only in Mormon "ordinances" and in the presence of Church leaders. In the first conference of the Church held on June 9th of 1830 in Fayette, New York, organizing his Church, Smith formalized the instructions to "oft" partake of the sacrament. Of this meeting, Joseph Smith wrote:

> *… we partook together of the emblems of the body and blood of our Lord Jesus Christ … Much exhortation and instruction were given; and the Holy Ghost was poured out upon us in a miraculous manner many of our number prophesied, whilst others had the Heavens opened to their view, and were so overcome that we had to lay them on beds, or other convenient places: Among the rest was Brother Newel Knight who had to be placed on a bed, being unable to help himself. By his own account of the transaction, He could not understand why we should lay him on the bed, as he felt no sensibility of weakness. He felt his heart filled with love, with glory and*

> *pleasure unspeakable, and could discern all that was going on in the room, when all of a sudden, a vision of futurity burst upon him. He saw there represented, the great work which through my instrumentality was yet to be accomplished. He saw Heaven opened and beheld the Lord Jesus Christ, seated at the right hand of the majesty on high, and had it made plain to his understanding that the time would come when he would be admitted into his presence to enjoy his society for ever and ever. When their bodily strength was restored to these brethren, they shouted, "hosannas to God and the lamb" and rehearsed the glorious things which they had seen and felt, whilst they were yet in the Spirit.* (Smith, 1843, pp. 41-42)

The relationship of the symptomology associated with this visionary experience highly suggests Joseph Smith surreptitious use of entheogenic material in the Mormon sacrament ordinance. Further, symptomology associated with Mormon visionary experience likely results in charges of medicating or doctoring the wine. Seeming to deflect this criticism onto those making the charges, Smith warned members in August 1830 they should not "partake" of wine "except it is made new among you" (Smith, 1835, p. 27). As he will do again in 1833, and in 1836 (see below), Joseph seems to suggest that any wine he administers during Mormon ordinances will be new wine, consecrated, and non-intoxicating.

1830-1831: Kirtland, Ohio, charges of intemperance

When Joseph Smith arrived in Kirtland, Ohio in 1831, converts had experienced visionary sacraments similar to that witnessed in New York. How did these Mormons, having not met Joseph Smith, institute an entheogenic sacrament? Mark Staker (2009, pp. 19-26) in his "Hearken, O Ye People" contextualizes the episode in 19th-century African American worship practices and the enthusiasms of the Second Great Awakening. However, there are reasons to believe that "wild enthusiasms" associated with early Mormon visionary meetings were more than just such reflections. For instance, a medically trained school teacher, Jesse Moss, who knew the nature of religious enthusiasms, reported that Mormon enthusiasms far exceeded those of the Methodists. A more likely possibility for early Mormon wild enthusiasms is one of the four Mormon missionaries who visited Kirtland and departed before the onset of the Mormon excesses described below. Mormon missionaries, including Frederick G. Williams (see above), stopped in Kirtland on their way to Independence, Missouri. In Kirtland, they converted most of Sidney Rigdon's Campbellite congregation, including Isaac Morley and Peter Kerr.

Unusual manifestations

In his book, *Hearts Made Glad: The Charges of Intemperance. Against Joseph Smith, the Mormon Prophet*, author Lamar Petersen noted during the early days of the Church there were "unusual spiritual manifestations" associated with the drinking of sacramental wine, behaviors of such a shocking nature it "*impaired the image of the young Church among sober people*" (Petersen, 1975, p. 79). According to Moss (1913), a medically trained school teacher in Kirtland, Ohio, offered testimony that Mormons,

> *took what was called the sacrament up at the [Isaac] Morley house. They were in the habit of turning everybody out of the door when they partook of the bread and wine, putting blankets up at the windows, shutting off the sight from without ... then [later] they opened the door and let us all come in again. [The] poor-house in Portage County, Ohio, where there were half a dozen insane and idiotic persons, was the best comparison of anything to the scene that night. And if I had had my cloak on, I would have stolen the wine and carried it home to see whether it was drugged or not.* (p. 384)

William S. Smith, testifying after Moss, supported the recollections of Mr. Moss:

> *I have attended the meetings at Mr. Morley's. ... in the house I have seen young men and women seemingly unconscious, and the folks said they had lain so for two days and they were there on their beds, and nobody tried to prevent us looking at them, but we were not allowed to go into the room.* (Ibid, p. 888)

On another occasion, Moss concluded that Mormon sacrament meetings "exceeded the wildest scene ever exhibited among the Methodists" and instead "became fully satisfied the wine was medicated," even attempting to secure a bottle for testing but was unsuccessful (Moss, 1878). Petersen also noted that "*the catalepsy could, of course, have been induced without the aid of wine [but the scene was] reminiscent of the first conference of the Church a year earlier at Fayette, New York*." That Moss indicated that Mormon enthusiasms exceeded that of the Methodists and lasting 24-48 hr, strongly supporting this conjecture of Smith including psychoactive substances in the sacraments.

Joseph Smith arrived in Kirtland, Ohio after the incidences discussed above but in time to preside over the June 6th, 1831 Elders conference. According to Levi Hancock (1858, p. 90) who was present as this meeting:

> *Joseph put his hands upon Harvey Whitlock and ordained him to the high Priesthood he [Whitlock] turned as black as [Lyman Wight] was white his fingers was set like Claws he went around the room and showed his hands and tried to speak his eyes were in the shape of Oval O's. Hyrum Smith said Joseph that is not God. Joseph said do not speak against this.* (Ibid)
>
> *It is likely that Joseph Smith, had considerable experience with entheogens, is not concerned with the chaos they create, and is reluctant to attempt to intervene. However, Joseph's brother was not convinced:*
>
> *I will not believe ... unless you inquire of God and owns it. [At this] Joseph bowed his head, and in a short time got up and commanded Satan to leave Harvey, laying his hands upon his head at the same time." ... [Then] Copley, who weighed over two hundred pounds, somersaulted in the air and fell on his back over a bench. Wight cast Satan out of Copley, and Copley was calmed. The evil spirit, according to Hancock, was in and out of people all day and the greater part of the night.* (Ibid)

Taken together, the events of the 1830 and 1831 conferences strongly suggest entheogenic influence and compares well with Joseph Smith's earlier entheogenic-facilitated early visions (Smith, 1830, pp. 276-267, 324-325).

Negative publicity

A letter to the editor of *Palmyra Reflector*, published in January 1831, accused Joseph Smith of *legerdemain*. Since this term referred then, as now, to "*Sleight of hand; a deceptive performance which depends on dexterity of hand; a trick performed with such art and adroitness, that the manner or art eludes observation*" (Webster, 1828), its use in this context may reflect ongoing accusations that Joseph Smith was manipulating the sacramental wine.

Sacramental wine was not the only possible carrier for an entheogen enhancing early Mormon sacramental experience. We have noted the entheogenic potential of ergot-infected rye, possibly mixed with the sacramental bread, like that which may have induced preternatural experiences in the life of Joseph Smith's great grandfather Samuel Smith. As we will see in discussing Mormonism's 1840s Nauvoo, Illinois period, ergot-infected rye was widely used as a medicinal remedy in Joseph Smith's day and may also have lent itself to more spiritual uses.

Complaints about Mormon enthusiasms drew the attention of the nation's newspapers. For instance, in the September 1831 edition of the *Vermont Gazette* (Bennington, Vermont), published a letter to the editor reporting: "*Some [Church members] lie in trances a day or two and visit the unknown regions in the meantime; some are taken with a fit of terrible shaking which they say is the power of the Holy Ghost*" (Kirkham, 1959). A trance lasting 24-48 hr is highly suggestive of *D. stramonium* intoxication (Bryson, 1996, p. 673; Wiebe, Sigurdson, & Katz, 2008). The *Independent Gazetteer* (Taunton, Massachusetts) reported on January 11, 1833 that during Mormon meetings there would be "*shoutings, wailing, fallings, contortions, trances, visions, speaking in unknown tongues and prophesying*" (Morgan, n.d.). Also, Henry Caswell (1843, p. 63) wrote of "a pretended sacrament" associated with manifestations of power in early LDS meetings. A pretended sacrament, although not stated explicitly, suggests drugged wine. So vociferous were Mormon critics that local Church leaders became alarmed and complained to Joseph Smith of similar undisciplined scenes. Table 2 summarizes what was reported by church leaders.

Table 2. Comparison of converts undisciplined scenes and Joseph Smith's first vision

Church leader reports	Undisciplined scenes
George A. Smith (1867)	Unnatural distortions
David Whitmer ("John Whitmer, History," 1831-*ca*. 847)	Extravagant and wild ideas Wielded the sword of Laban as expertly as a light dragoon Acted like an Indian ... scalping Slid on the floor with the rapidity of a serpent, sailing in boats to preach to the Lamanites
Parley P. Pratt (Bushman, 2005, p. 151)	Swoons
Joseph Smith's First Vision (from Table 1)	Unseemly gestures Cramps Falling into ecstasies Insanity Bound hand and foot in chains as immovable as a stick of timber Getting on the stumps of trees and shouting Pursuing balls flying in the air Running off a cliff, nearly being killed in pursuit of a floating croll

Although Joseph Smith chastised Isaac Morley in whose house many of the sacrament meetings occurred, Smith failed to acknowledge their similarity to his own first 1820 vision of God, his 1823 visions of an angel and golden plates, and the 1829 scrying visions while translating *The Book of Mormon*. Similar problematic scenes beset meetings Smith conducted. At Kirtland sacrament meeting in 1831, Joseph Smith suggested imminent mass visions and promised Lyman Wight he would have a vision of Christ. Mormon historian, Richard Bushman, explains what happened next: "*Wight turned stiff and white, exclaiming he had indeed viewed the Savior ... Joseph himself said, 'I now see God and Jesus Christ' ... Then Harvey Whitlock ... turn as black as Lyman was white ... his fingers were set like claws. He went around the room and showed his hands and tried to speak, his eyes were the shape of ovals "O's" ... [Then] Leman Copley, who weighed over two hundred pounds, somersaulted in the air and fell on his back over a bench ... [Similar behavior was manifested by] people all day and the greater part of the night*" (Bushman, 2005, pp. 156-157). These experiences, likely following the administration of the sacrament with Joseph present, are difficult to explain absent some toxidrome, yet easy to explain in the presence of one, and are strikingly similar to those described in Smith's own first vision and those that took place in early Kirtland, possibly under the direction of Peter Kerr, a former slave known as "Black Pete" in early Mormon literature.

Peter Kerr

According to Mark Staker (2009), after the missionaries left Kirtland later in 1830, 55-year-old Peter Kerr ("Black Pete") acted as "a revelator" and "a chief man" to a small Mormon community in Kirtland, Ohio, until Joseph Smith arrived in early 1831 (pp. 77, 79). Kerr was raised by a mother whose religious tradition was the syncretic African-Muslim religious tradition of what is now the Ivory Coast. When enslaved, she lived along the Monongahela River in western Virginia where Peter was likely raised in an ecstatic religious fusion of African, Baptist, and Methodist ideas that included "*interacting with the spirit world, dancing in fire, and speaking in tongues*" (p. 11). It is therefore likely that Kerr had exposure to African folk magic, conjure, and root medicine and knowledge of *D. stramonium*.

According to Catherine Yronwode, "root doctoring" mixed African magical practices with American Indian herbal medicine. Further, "most medical herbs also have magical uses, so urban conjures were able to take advantage of the medical industry's commitment to herb purity and specificity" (2002). Among the visionary materials used by Native Americans was jimson weed or *D. stramonium* (see Schultes, 1975), a substance also used in African medicine (Hamby, 2004, pp. 39, 54).

According to Staker (2009, p. 34), Kerr was "*among those brought into the Reformed Baptist movement in early 1828*" and not until late 1830, a period of nearly 3 years, that he converted to Mormonism and "*was recognized as a 'revelator' among them*" (Ibid, p. 119). If Kerr was solely responsible for the entheogenic-infused enthusiasms in early Mormonism, why didn't the same enthusiasms appear after he joined the Reformed Baptists in 1828? It seems more likely that one of the missionaries noted that like Joseph Smith, Kerr was a "*charismatic with a distinctive religious perspective*" (Ibid, p. 3) and concluded he was the logical choice to minister to converts' spiritual needs. As Staker states, "*Kirtland's religious enthusiasm was similar in so many ways to the religious world Black Pete knew that it is unlikely it developed as an independent experience*" (Ibid, p. 171). It would have been surprising, given Kerr's background and the likely promptings of at least one Mormon missionary, had he not utilized *D. stramonium* in his visionary syncretism.

For several months, Kerr (like Joseph Smith would do later when he arrived in Kirtland) introduced converts to entheogenic facilitated visions and spiritual ecstasies bringing many into the nascent Church. Further, like Smith's use of datura, Kerr's administration of this anticholinergic entheogen was problematic, leading to an embarrassed Church and accusations of medicated wine.

In 1833, Joseph Smith blamed the enemies of the Church for the medicated wine. In an 1833 revelation, it was advised, "*in consequence of evils and designs which do and will exist in the hearts of conspiring men in the last days ... your sacraments ... should be wine, yea pure wine of the grape of the vine of your own make*" (Smith, 1835, pp. 207-208).

Prejudice and secrecy

Joseph Smith's surreptitious use of entheogenic material was a closely guarded secret for obvious reasons. Although the ingestion of such substances was not illegal in the 19th century, their use was discouraged by withering ridicule. In a telling passage of *The Book of Mormon*, Joseph psychologically prepared early converts for the ridicule they might face and primed them to embrace it. This persecution incorporated, into *The Book of Mormon* that associates an entheogenic tree and the hostility of his neighbors, "*And after they had a tasted of the fruit, they were ashamed, because of those that were scoffing at them*" (Smith, 1830, p. 20).

Smith even faced strong opposition from his family. In a family gathering: Joseph Sr. began to speak of the discovery and translation of *The Book of Mormon*. At this, [his cousin] Jesse grew very angry, and exclaimed, "*If you say another word about that Book of Mormon, you shall not stay a minute longer in my house, and if I can't get you out any other way, I will hew you down with my broad ax*" (Smith, L. M., 1853, pp. 154-156). Although Jesse's heart eventually softened and he reconciled with his cousin, such prejudice against the visionary, magico-religious practices of Joseph Smith Jr. required that he make considerable efforts to conceal his selective use of entheogens.

1833: Kirtland, Ohio School of the Prophets and the Mormon Pentecost

In 1833, visionary endowments associated with washings, anointings, and sacramental wine during sessions of the "School of the Prophets." For example, in a March 1833 meeting of high priests, "*Bro Joseph ... [gave] a promise that the pure in heart that were present should see a heavenly vision ... after which the bread and wine was distributed by Bro Joseph after which many of the brethren saw a heavenly vision of the savior and concourses of angels and many other things*" (Roberts, 1902). During this period, on-demand visions again suggest the administration of an entheogen. Mormon elder Zebedee Coltrin reported Joseph Smith confidently promising Coltrin and Oliver Cowdery, "*Now brethren we will see some visions,*" after which Smith verbally guided them through a trip to heaven, where they saw Adam and Eve seated on a golden throne that looked like a celestial lighthouse (Anderson, D. S., 2018).

Between 1833 and 1836, we have no reported visions such as seen in New York or early Kirtland period. The embarrassment to the Church and various accusations surrounding Mormon visionary experience necessitated a change in venue. Smith would build a temple to house convert visions before the next series of reports of drugged wine would emerge.

The spiritual outpouring associated with the dedication of the Kirtland Temple in March and April of 1836 was called the Mormon Pentecost, the equivalent to the early Christian Pentecost that was also accused of alcohol intoxication. Visionary experiences during this period are linked, we argue, to the administration of bread and wine sacraments and oil anointings. Although not exhaustive, these remembrances are pertinent to the question of entheogen-infused Mormon ordinances and visionary experience.

The Kirtland temple endowments created a sacred space decorated with labyrinths, gonfalons, spirals, and squares within squares (Howlett, 2014) and a prolonged ceremony that included a day of fasting and the "*reenactment of the Passion narrative and Pentecost*" (Olaiz, 2014) that included the washing of feet and anointing the head with holy oil. In the evening, the fast was broken with a communion of bread and wine as a "reenactment of the Last Supper" followed by a ceremony that "*mimicked the high point of Christian redemption ... they stayed up all night ... a re-enactment of Gethsemane*" (Ibid). In serving the wine, Joseph Smith explained, "*the wine was consecrated, and would not make them drunk ... they began to prophesy, pronouncing blessings upon their friends*" (Harris, 1841, p. 32).

With increasing confidence in his entheogenic sacraments, Joseph Smith enabled hundreds to received visions during the dedication ceremonies of the Kirtland temple, but only if willing to participate in the Mormon ordinances. Smith's exuberance, however, was tempered as the manifestations of anticholinergic toxidromal symptoms led, once again, to accusations of drugged wine. For instance, a Church member with the last name of McWhitney complained that the wine consumed in the temple ordinances was actually "mixed liquor" and that "*the Mormon leaders intended to get the audience under [its] influence*" so visions experienced were believed to be of "the Lord's doing" (1888, p. 135). John W. Gunnison interviewed the Church elders present at the 1836 Kirtland Pentecost and reported: "*Wine was administered ... that had been consecrated and declared by the Prophet to be harmless and not intoxicating. This ... produced unheard of effects, if we may credit the witnesses of these proceedings. Visions, tongues, trances, wallowings on the ground, shoutings, weeping, and laughing, the outpouring of prophecies ... these and other fantastic things were among 'the signs following' at Kirtland*" (Gunnison, 1852, p. 107)

Even though descriptions of visions and ecstasies associated with entheogenic sacraments and anointings at the Kirtland temple were inspirational and stirring, problems developed almost immediately. Soon afterward accusations of adultery beset Joseph Smith as did challenges to his leadership, a Mormon war in Missouri, and the failure of the Kirtland Anti-Bank society. These catastrophes would occupy Smith's attention and prevent him from creating an environment suitable for entheogen administration. It would not be until the Smith had established the City of Nauvoo, formed the Nauvoo Legion to protect him and the Saints, and completed a new temple would he again promise mass visionary experience.

1842: Nauvoo temple

In 1841, Joseph Smith laid the cornerstone of a new temple in Nauvoo, Illinois, and in May of 1842, Smith taught a lengthy Masonic-like initiation rite to trusted leaders. The purpose of the training was to prepare for the dedication of the temple (Smith, 1977, p. 237). Since the temple was not completed and likely not wishing to repeat the embarrassment associated with the open access to the Kirtland visionary period, there were no visions during this initial endowment, and there were none promised. However, the expected endowment planned for the completed Nauvoo would eclipse those of the Kirtland Pentecost. Smith explained,

> *I spent the day ... instructing them in the principles and order of the Priesthood, attending to washings, anointings, endowments ... by which anyone is enabled to ... come up and abide in the presence of the Eloheim ... [as] soon as they are prepared to receive, and a proper place is prepared to communicate them, even to the weakest of the Saints [see D&C 89:3]; therefore let the Saints be diligent in building the Temple.* (Smith, 1977, p. 237)

The Edenic tree

The organization and context of the anticipated Nauvoo endowment provide for the covert administration of entheogenic anointings and sacraments, although for this endowment, the sacrament included partaking of the fruit from the tree in the Garden of Eden. Following purifying ceremonies of washing and oil anointing, a "new name" was given to initiates, who were informed was connected with Christ's promise in Revelation 2:17 of a "white stone" (Van Dusen, 1847). Then, fruit representing the forbidden fruit of "the tree of knowledge of good and evil" was plucked from the tree and eaten by the initiate. The Nauvoo endowment would avoid the problems of mass entheogenic visionary experience by conducting initiates in small groups within the seclusion of the temple. Receiving this sacred food also fulfilled the *other* promise of Revelation 2:17 - that they would be given "to eat of the hidden manna." Their initiation followed both the pattern of alchemical freemasonry with its entheogenic elixir and philosopher's stone and the pattern set by Joseph Smith when he ate of "hidden manna" and acquired his "white stone." Following this, the initiates engaged in an interactive entheogenic journey through the fall of Adam and the redemption of man by Jesus Christ after which they would pass through a curtain into a beautifully decorated celestial room and the presence of God (Buerger, 2001; Hyde, 1857).

We argue that to fulfill his promise of coming into the presence of God in the Nauvoo temple, Joseph Smith would have offered:

1. An overall sense of the holy and a mindset of sacredness.
2. An impressive and uplifting multistoried edifice with esoteric symbols inside and out and multiple special purpose rooms.
3. Trusted attendants to guide initiates through each aspect of the ceremony, to prompt attendees should they experience confusion and provide assurance if distress occurs, and
4. An entheogen that would not produce the indecorous symptoms and outside criticisms such as the Church experienced during the visionary Kirtland period.

After receiving the new name, an entheogenic anointing, and ingesting Edenic fruit, converts basked in emotional and physical safety designed to provide spiritual experiences of such consequence it would enhance the joy of living and provide comfort during periods of struggle.

Nauvoo Entheogen

The procurement of an entheogen for the Nauvoo temple would not be as easy as harvesting datura seeds found growing in the surrounding countryside and used as ornamentals in some gardens. Because of the Kirtland experience, datura as an entheogen would draw unwanted attention. And gathering enough entheogenic mushrooms for the rapidly increasing Church population, at time around 10,000, was not practical. However, several physicians in positions of Church leadership would have known about the medical use of ergot in obstetrics and could easily extract ergot's water-soluble entheogenic component. In Nauvoo, ergot was readily availability, easy to hide, and of high potency making it an ideal entheogen for burgeoning Church population. However, by 1842, two important physicians in the Mormonism, Luman Walters and John C. Bennett, became disaffected with Joseph Smith and a third, Frederick G. Williams died. Another physician, Williard Richards, may have been able fill these vacancies, but in 1843, the malpractice trial of doctor William Brinks may have persuaded Joseph that an ergot-derived entheogen could become very problematic.

A year before the 1843 trial, Dr. Brinks treated a female in labor suffering from severe pain and fever. When he treated her with ergot to hasten delivery, her womb "lacerated or ruptured" (Dinger, 2016, p. 85). In his defense, Dr. Brink explained, "*I gave her ergot ... nothing but what any physician would do*" (The Joseph Smith Papers, 1842-1844). However, Dr. Samuel Bennett, a traditional doctor, testified against Dr. Brink, stating that he "*should not have administered ergot ... its effect on the uterus [is] to expel the contents of the uterus [or] to produce delivery*," but ergot caused increased intrauterine pressure, rupture, and permanent disability (Dinger, 2016, p. 85.) The case was high drama and 3 months later, Joseph Smith meet with Native American leaders in what appear to be negotiations for a safer, more effective entheogen - peyote.

Peyote entheogen

During the period of Indian Removal beginning in 1830, Native Americans living east of the Mississippi River passed through Nauvoo on their way to their seasonal hunting grounds. Potawatomi delegations, including members of the Fox and Sauk nations, visited Joseph Smith between April 18 and August 28 of 1843 (discussed below). The purpose of these negotiations is not altogether clear to historians. However, as we will see, the negotiations probably involved Joseph Smith giving valuable and sacred property to the Potawatomi without apparent gain to Smith in return. We suggest that Joseph Smith negotiated with nearby Native Americans for the delivery of peyote to Nauvoo for the Nauvoo temple endowment.

Quest for a new entheogen

There were several groups of Native Americans living on the American Prairie in the early 19th century, any of which could have provided for the transport of peyote from South Texas. Joseph Smith has had dealings with the Prairie groups of the Potawatomi, Fox, Sauk, and Delaware (Lenape), with Smith sending missionaries to the Mahican, Sioux, and other Indian peoples residing in Wisconsin and Canada (Jensen, 2012; Mahas, 2017; Walker, 1993). Further, although few Indians joined Mormonism, there were "many among the Shawnees" who believed in Smith's mission (Byron, 1993).

The Potawatomi

The Potawatomi were an Algonquian-speaking Eastern Woodlands group related to the Ojibway, discussed in relation to *D. stramonium* and *A. muscaria*. However, with the Indian Removal Act of 1830, "*the Potawatomi were removed in two groups: The Prairie and Forest Bands from northern Illinois and southern Wisconsin went to Council Bluffs in southwest Iowa, and the Potawatomi of the Woods (Michigan and Indian bands) relocated to eastern Kansas near Osawatomie*" (Bassett, 2016).

Peyote "*was used in ancient times in Mexico, spreading from the Rio Grande Valley and taking hold on the Plains [the American Prairie] as early as the 1840s*" (White, 2011, p. 178). Peyotism existed among Native American shaman and medicine people for centuries and was likely used by Potawatomi and other Plains Indian shamans before they formally adopted the Peyote Religion in the 1890s (Stewart, 1987, p. 93). The Potawatomi passed through Nauvoo on their way to and from their hunting grounds in Iowa territory (Smith & Edwards, 1972) and could have served as an early bridge between the Indians of the Southwest (e.g., Comanche-Osage) and Joseph Smith for the delivery of peyote to Illinois for the Nauvoo temple. Prairie Potawatomi began actively trading peyote imported from South Texas at least by 1870 (Schaefer, 2015) and perhaps even earlier (Howard, 1962).

In August 1841, a large group of Fox and Sauk Indians, including 100 chiefs, visited Nauvoo in 1841 (Appanoose-Biography, n.d.) with their leader, Chief Keokuk, forming a personal relationship with Joseph Smith and his wife, Emma. Emma exchanged recipes for herbal medicines with the wife of Chief Keokuk (Newell & Avery, 1994, p. 278). During the spring and summer of 1843, three delegations of Potawatomi traveled to Nauvoo primarily to ask Joseph Smith "*for assistance and advice in their struggles with white Americans*" and in April 1844, eleven Potawatomi Indians visited Smith again "seeking help to avoid losing their land" (Council of Fifty, 1844-1846). Joseph Smith had a significant number of Native American contacts during the Nauvoo period, any of which could have provided for the delivery of peyote to Nauvoo; we feel it was most likely with the Potawatomi.

Besides this encounter, there were additional meetings between Joseph Smith and the Potawatomi. According to LDS Church Historian Jay Todd (1968), in June 1843,

> *Several of the Potawatomi Chiefs called to see the Nauvoo House and Temple ... Nauvoo was a prominent spot for Indians and was called by them Quashquema ... [and] Indian burial grounds abounded in the area." However, not finding Joseph Smith present, the Potawatomi explained, "They were not free to talk, and did not wish to communicate their feelings until they could see the great Prophet."* (Ibid)
>
> *They returned in July and told Smith, "We have talked with the Great Spirit, and ... the Great Spirit has told us that he had raised up a great Prophet ... We will now wait and hear your word."* (Ibid) *After Smith spoke, Smith had an ox killed for them and they were given fresh horses for their journey home.* (Ibid)

During one of the several visits of Potawatomi to Nauvoo, Joseph possibly gave the Potawatomi captain a significant portion of the Egyptian papyri from which he "translated" a work of scripture said to have been written by the hand of the Biblical Abraham (Todd, 1969). These papyri were from a larger collection purchased by Joseph Smith in 1835 for $2,400 (Gee, 2007; Remini, 2002, p. 105). The value of these papyri was significant since $2,400 in 1835 represents nearly $70,000 adjusted to 2019 value. It is a mystery why

Smith would give away such valuable papyri when he anticipated showing them on display for a fee, and also anticipated translating the "Book of Joseph" from the same collection of papyri (Larsen, 1992). The gesture is striking.

Was Smith negotiating for access to Native entheogens? Such negotiation is suggested by the timing of these interactions with the Potawatomi, Fox, and Sauk, beginning within weeks of the discrediting of ergot in the Brink trial, by Smith's inordinate "gift" to these representatives, and by earlier exchanges of herbal information between the Smith family and the family of the local Sauk chief Keokuk. Acquiring Native American entheogens could have fueled a new and more profound spiritual Pentecost in the endowment to be given in the Nauvoo temple, scheduled for completion in 1845-1846.

Lyman Wight

Joseph Smith's vision was for Mormon colonies to span the globe, with Independence, Missouri being the center of a worldwide kingdom of God. After the Mormon War of 1838, Smith moved the center of the kingdom to Nauvoo, Illinois but still sought to establish colonies adjacent to Indian Territory in areas such as California, Oregon, Minnesota, the Great Basin, and Texas (The Joseph Smith Papers, 1842-1844, pp. 55, 170, fns 46-47). Smith's emissaries also negotiated for the Neueces strip (Figure 30) in deep south Texas, an area extending from Corpus Christi down the coast to Brownsville, then westward between the Rio Neueces and the Rio Grande River.

Figure 30. The Neueces strip shown in pink and white stripes. Adapted from the U. S. Army Campaigns of the Mexican War (Carney, n.d.). In Figure 25, the same area is shown in the purple-blue area.

Lyman Wight, having experienced an entheogenic vision of Christ as documented above, became a reliable friend of Joseph Smith and resolutely carried out his orders, including being part of a Mormon pinery colony in Wisconsin. Joseph Smith used such colonies, flung out from the Church's central hub at Nauvoo, to acquire resources for the main body of the Church. The Mormon colony in Wisconsin, between 1841 and spring 1845, floated timber to Nauvoo amounting to "*1.5 million board feet of milled time, more than two hundred thousand shingles, and a large number of miscellaneous logs, barn board, and timbers*" (Clark, 1997-1998, p. 67). In February 1844, Lyman Wight, in conversation with local Wisconsin Native Americans, concocted a plan to form a joint Mormon-Indian colony in Texas. Wight wrote to Smith requesting permission for himself and the Native Americans to travel to Texas to initiate such a colony (Figure 31). Smith agreed, and Wight was ordered "*to take a small colony to Texas and make smooth and ready the path for a major migration of the L.D.S. church to Texas*" (Banks, 1945; Johnson, 2006, p. 5). However, given the Mormon emphasis, since 1829, on building settlements near Native American lands, and given that the initial colony idea proposed by Wight was to be a Mormon-Indian colony, it seems highly probable, if not nearly inevitable, that Woodworth would have entered into contact with Native Americans there.

Joseph Smith aimed to establish colonies to procure resources for the body of the central hub of the Mormon community at Nauvoo. What resource was the planned Texas Mormon-Indian colony intended to provide? Texas was a keystone to peyotism; peyote grew in abundance in Southwest Texas, especially along the Texas-Mexico border and the Rio Grande River, with an active peyote trade that only abated in 1959 (Morgan & Stewart, 1984). In this expedition, Joseph Smith may have attempted to plant a Mormon-Indian colony in the heart of peyote country, where his colony could harvest thousands of peyote buttons, just what the thousands of Nauvoo saints would need if peyote was the entheogen used in the completed Nauvoo temple.

Did Joseph Smith know he was planting his prospective colony where Mormon colonists could acquire peyote? Smith's evident use of entheogens, his need for them to replicate the Kirtland Pentecost, the timing of the Texas negotiations shortly after other potential entheogens and sources of entheogens faltered, his intention to involve Native Americans in his scheme, his pattern of planting colonies to supply resources from the local environment, and his choice of *the* peyote environs suggest to us his intention to use his Texas colony to supply peyote. In addition, tangible, artifactual evidence exists indicating that Joseph Smith knew and was interested in the peyote trade and had contacted a peyote trade network of Native Americans through intermediaries, or directly from the anticipated Texas Mormon colony, or both. A sacred stone found among

Smith's belongings, which we will call "the peyote stone," is that artifactual evidence.

Joseph Smith's Peyote Stone

Among Joseph Smith's possessions during his death was a finely tooled sandy-colored seer stone (Figure 32), unlike any other he used for scrying (Quinn, 1998, pp. 246-247, Figure 10). The stone is smooth in texture with a hole through the center surrounded by eight smaller indentations of alternating sizes where the central flower and tuffs of the peyote button have been cored out. It is comparable to the eight-lobed peyote button in Figure 33. The coin-like ridged circular edge of Smith's stone not seen on the peyote button signifies the visionary nature of peyote. The alternating sizes of the indentations on this stone are somewhat similar to the peyote button and are comparable to the alternating size of the tufts in Figure 33, an eight-lobed Plains Indian peyote pouch (Figure 34) currently displayed in the Plains Indian Museum in Cody, Wyoming (see Hultkrantz, 1997, p. 6).

Figure 34. Eight-lobed peyote pouch (image from the Plains Indian Museum in Cody, Wyoming).

The nomadic aboriginal peoples of the American Plains included the Lipan Apache, Tonkawa, Comanche, Kiowa, Otto, Osage, Arapaho, Sioux, and Pawnee, bordered on the northeast by the Ojibway, Potawatomi, Sauk, and Fox. Most of these groups were relocated, westward into Plains Indian territory following the Indian Removal Act of 1830 and interacted with Joseph Smith (Walker, 1993, pp. 6-7). For instance, by the 1840s, the Potawatomi had been resettled west of Nauvoo, Illinois, within the cultural boundaries of the Plains Indian groups, providing an opportunity for the transmission of information about peyote to Joseph Smith.

According to Omer Steward (1974), "*The Lipan Apache Indians in the vicinity of Laredo, 1760 to 1850s, learned of the properties of Peyote and the ritual for its use from Coahuiltecan-speaking Carrizo and Tonkawa and in turn taught Peyotism to the Comanche and Kiowa*" (p. 211), their northern allies by 1830 (p. 215). A possible route for the spread of peyotism toward the northeast from Texas proposed by Steward (pp. 215-216) and included in the report by R. A. Smith (1961) states, "*The demand for Mexican livestock, captives, and plunder increased after American commissioners made treaties of amity and trade with the Indians of the South Plains in the 1830s. The Comanche and Kiowa consequently stepped up their predatory raids below the Rio Grande ... Their deepest penetrations of Mexico put the Indians at points a thousand miles straight south of their home range in Kansas and Oklahoma ... One can suspect the warriors might also have learned about and experimented with the little spineless cactus, peyote, which grew in the area.*"

The intricate patterning on Joseph Smith's peyote stone in Figure 32 above may be a Native American stone gorget such as the stone in Figure 35 belonging to David Whitmer one of the three witnesses to the angel and golden plate and used as a seer stone. Native American gorgets, worn around the neck as signs of goodwill or an indication of status, and Smith's peyote stone, although of Native American origin, is not typical of a Native American gorget. Instead, it is similar to the pre-Columbian stone whorl from Mixtec, Mexico, shown in Figure 36. Joseph Smith's stone appears to be a Native American visionary peyote stone effigy. Similarly made pre-Columbian visionary stone effigies appear to represent the *I. alvarus* toad in Figures 35 and 36. Further, the Native Americans of the Lower Pecos region of southwest Texas have a history of ritual peyote use and the manufacture peyote effigies extending back 5,000 years (Powell, 2017; Terry *et al.*, 2006).

Figure 35. Gorget seers stone belonging to David Whitmer (courtesy: Signature Books).

Figure 36. Pre-Columbian Aztec stone spindle whorl (photo by Christophe Helmke).

Peyote has tufts of "hair" on each of its lobes and a central flower that if removed, leave a corresponding number of depressions. Native art, such as the peyote pouch in Figure 31 depicts peyote by the several circular depressions or tufts, often five or eight, surrounding a central circle or hole. The representation can further be stylized in native art by showing the tufts or depressions as alternating in size around the button as in Figure 32. An examination of Joseph Smith's stone shows precisely this same stylization. The stone consists of a central circle surrounded by eight circular depressions arranged in an alternating pattern of large-small-large.

Joseph Smith's peyote stone in Figure 32 above bears a striking resemblance to Figures 37-39 (frames from a video produced by DiezyMedia in 2007). In Figure 37, the transfixed, partially transformed shaman is holding a smooth-edged cactus, but in Figure 38, the shaman's eye is wide open, and reflecting a partial transformed eight-lobed peyote button that had five lobes in Figure 37. In Figure 39, the consumed peyote button has further undergone entheogenic transformation amidst "spiritual light" pouring from its scalloped edges. In comparison, a reduced image of Joseph Smith's peyote in Figure 40 favorably compares to the visionary portrayal of the Huichol peyote button reflected in the shamans eye in Figure 41. Figure 41 shows the shaman in spirit and endowed with new powers.

While ownership of the peyote stone transferred to his heirs after his death, how this curious stone came to Joseph Smith is unknown. Quinn (1998, pp. 246-247) speculated this stone, which was one of the seer stones Brigham Young had mentioned Joseph finding at Nauvoo on the banks of the Mississippi. However, considering the information above, it is likely a tooled stone that was hand-tooled by a Native American familiar with peyote. Joseph Smith owned other hand-tooled Native American stones used for divination, as other early Mormons did, each one tooled by a Native American (Quinn, 1998, p. 247). For instance, the Whitmer family, followers of Joseph Smith from the 1820s, used two hand-tooled Native American gorgets with holes bored into them as seer stones (Quinn, 1998, Figures 11-13). Further, research conducted on these stones by Mormon scholars aside from Quinn has uniformly identified them as tooled by Native Americans (Ashurst-McGee, 2000, p. 165; Murphy & Baca, 2016, p. 707). The peyote stone broadly resembles Native American gorgets but has a more intricate representation carved into it, and compares well to Native American representation of peyote.

Lyman Wight, Mission to Texas

Joseph Smith's vision was for Mormon colonies to span the globe, with Independence, Missouri being the western hub a worldwide kingdom of God, Jerusalem being the eastern hub. After the Mormon War of 1838, Smith moved the center of the kingdom to Nauvoo, Illinois along with his converts; simultaneously, he attempted to establish colonies adjacent to Indian territory in areas such as California, Oregon, Minnesota, the Great Basin, and Texas (The Joseph Smith Papers, 1842-1844, pp. 55, 170, fns 46-47). The purposes of these colonies were twofold: (a) expand the Kingdom of God until it filled the earth and (b) provide a place where, if another Moron War were to break out, the Mormons could find protection.

How did Joseph Smith acquire a peyote stone? Given that peyote was grown at the Texas-Mexican border, and Joseph Smith sent a scouting-and-negotiating team to south Texas to establish a Mormon-Indian colony on the Rio Grande, it represents one of two possible modes by which the peyote stone traveled from the hands of a peyotist in Texas to those of Joseph Smith in Nauvoo, Illinois. In 1844, Smith sent a Mormon expedition to persuade Sam Huston to allot lands then disputed by the Texans and the Mexicans. These lands included the entire Neueces strip (Figure 30) extending from Corpus Christi down the gulf coast to Brownsville, then westward between the Rio Neueces and the Rio Grande Rivers encompassing the northern reaches of peyote inhabitation.

Just weeks after the Texas expedition party's return, Smith tasked Lyman Wight to establish a Texas colony, gave him a seer stone, and told him he would need this stone to receive revelation pertaining to his colonization work (Johnson, 2006, pp. 30-31). The stone Smith gave Wight was a seer stone, but not the peyote stone he retained until his death.

With the single exception of giving Oliver Cowdery his brown seer stone in 1829, Smith is not reported to have given anyone else such a stone until he gave this one to Wight in April 1844. This unique action on Smith's part and its timing are both readily explainable if the negotiating party delivered the peyote stone to Smith in Nauvoo.

Also noteworthy is that Joseph Smith gave Lyman Wight not just any seer stone but specifically a white stone. We have noted above that the "white stone" has a place in Joseph Smith's biography, biblical interpretation, and theology. Drawing on Jesus' promise in Revelation 2:17 ("KJV"), the young Joseph Smith had searched for a "white stone" to use in scrying. This biblical promise of receiving a "white stone" also included the promise of receiving "the hidden manna to eat," a promised gift that appears to have materialized for Smith as *A. muscaria* mushrooms or datura in the family's "sacred grove."

Since Smith's own experience of becoming a seer included obtaining a "white stone" used to find entheogenic "hidden manna," Smith's bestowal to Wight would have been only a halfway-boon had he stopped there. Joseph Smith's instructions to Lyman Wight on how to be a seer on the same pattern as Smith would have included instructions on using "hidden manna" as an entheogen to facilitate Wight's experience of second sight.

Some researchers have concluded that the "manna" in Judeo-Christian scripture was a psychoactive variously identified as a water-soluble extract of ergot (Merkur, 2000) and the *A. muscaria* mushroom, also known to some as the white stone. (Allegro, 1970; Irvin, 2009). Such a reading was known in early Christianity judging by the number of works of art featuring the *A. muscaria* and psilocybin-containing mushroom (Brown & Brown, 2016; Merkur, 2014; Rush, 2011). Joseph Smith, if he had not learned it from a mentor, had his own experience with entheogens, which would have led him conclude that entheogens were used in Judeo-Christian religion. It would be reasonable to believe that Joseph Smith would want to transmit his entheogenic knowledge to a trusted friend who had successfully ingested entheogens. Lyman Wight had responded well to the administration of an entheogen in 1831 when he "turned white" and "saw the Savior" (Hancock, 1858, p. 90) and remained a loyal friend to Joseph Smith even after Smith's death. It seems apparent that Wight's experience and loyalty resulted in Smith's gift of a white stone to locate entheogens in Texas. Apparently successful, Wight would have visions of Smith himself, years after the latter's death (Blythe, 2014; see also Johnson, 2006). Wight could easily carry 20,000 peyote buttons weighing 60 pounds to Joseph Smith in Nauvoo.

The end of visionary mormonism

The end of visionary and ecstatic Mormon can be causally associated with the death of Joseph Smith. Only a few of the many Mormon schisms that successors organized proved to be visionary. Those are visionary Mormon-Native American syncretisms that use peyote as an entheogen. Only one of Smith's descendants is reported to have used entheogens to facilitate spiritual growth and wished to introduce it as a general form of religious worship.

Death of Joseph Smith

Friction between Mormonism and their Missouri neighbors increased to the breaking point, and war broke out with Joseph Smith barely escaping with his life and the body of Mormons moving north in Illinois (Baugh, 2000). After fleeing Missouri, Smith established a new city that he called Nauvoo, the Beautiful along the eastern banks of the Mississippi River. Anticipating continued contention with non-Mormons, Smith formed a theocracy with political and military branches (Hansen, 1960, 1967). After Mormons deserters published an inflammatory first issue of the Nauvoo Expositor, Joseph Smith as the mayor of Nauvoo and general of the Nauvoo Legion ordered the destruction of the press.

Schismatic Mormonism

Within a century following the death of Joseph Smith, Mormonism splintered into over 200 schisms that collectively boast worldwide membership of over 16 million. The largest Mormon denominations are The Church of Jesus Christ of Latter-day Saints, The Community of Christ (formerly the Reorganized Church of Jesus Christ of Latter Day Saints), and groups collectively called Fundamentalist Mormons who still practice polygamy (Shields, 1982).

The leaders of these schisms each claim to be the legitimate heir to Joseph Smith, and prophet leader of their only true Church. Each schism attempts to maintain Mormonism as it was under Joseph Smith's leadership, including teaching his doctrine, believing his revelations, build temples, and performing his ordinances. For instance, in 1846, Brigham Young conducted temple endowments in the Nauvoo temple, as he understood Joseph Smith intended, including oil anointing, and raisins plucked from an Edenic tree (Buerger, 2001). However, to the disappointment of many, no religious visions or spiritual ecstasies were reported.

Return of the Egyptian Papyri

In winter 1846 as Brigham Young led the first contingent of Mormon's westward out of Illinois and across the Mississippi River and into Iowa where they camped. While there, a Potawatomi Captain inexplicably presented Brigham Young with "*two sheets of the Book of Abraham [papyri]; also, a letter from their 'Father' Joseph Smith, dated 1843, and a map of their land by W. W. Phelps*" (Todd, 1968, p. 40). Had Joseph Smith arranged for the Potawatomi captain to deliver peyote to Nauvoo and exchanged a peyote stone for Egyptian papyri as a token of their bargain, then the return of the papyri following Smith death solves the mystery.

Successors' negative views of visionary symptomology

Joseph Smith told early converts to expect somatology-associated religious visions and spiritual ecstasies. To prepare converts for the entheogen-facilitated spiritual manifestations and associated symptomology, Joseph Smith (1839, pp. 18-19) explained:

> *It is more powerful in expanding the mind, enlightening the understanding, and storing the intellect with present knowledge, of a man who is of the literal seed of Abraham, than one that is a Gentile though it may not have half as much visual effect upon his body; for as the Holy Ghost falls upon one of the literal seed of Abraham, it is calm and serene; and his whole soul and body are only exercised by the pure spirit of intelligence; while the effect of the Holy Ghost upon a Gentile, is to purge out the old blood, and make him actually of the seed of Abraham. That man*

> *that has none of the blood of Abraham (naturally) must have a new creation by the Holy Ghost.*

Therefore, stark was the difference between the many visions reported in early Mormonism and lack of similar reported after Joseph Smith's death, which distressed members inquired of their leaders. Mormon Apostle George A. Smith responded to these concerns in an 1867 discourse in Salt Lake City:

> *The question has often arisen among us, why it is that we do not see more angels, have more visions, [and] do not see greater and more manifestations of power?* (Smith, 1867, p. 10)

What followed is revealing. Apostle Smith recalled that in 1836, a filled Kirtland temple with over four hundred men of the priesthood, most of whom witnessed,

> *great manifestations of power, such as speaking in tongues, seeing visions, administration of angels. Many individuals bore testimony that they saw angels, and David Whitmer bore testimony that, he saw three angels passing up the south aisle, and there came a shock on the house like the sound of a mighty rushing wind, and almost every man in the house arose, and hundreds of them were speaking in tongues, prophesying or declaring visions, almost with one voice.* (Ibid)

Then, Apostle Smith diminished the value of these experiences when he noted that,

> *A number of them who manifested the greatest gifts, and had the greatest manifestations have fallen out by the way side, you look around among us and they are not here ... . But where you find men who have turned away, and have got terribly afflicted with self-conceit, you will find those, who, on that occasion and similar occasions, received great and powerful manifestations, and when the spirit came on them it seemed to distort the countenance, and caused them to make tremendous efforts in some instances.* (Ibid)

Reflected in George A.'s next remarks is the post-Joseph Smith Mormon attitude regarding public religious manifestations and spiritual ecstasies. Speaking favorably of nonvisionary post-Smith "revelation" by inspiration, George A. spoke of faithful converts,

> *who received the knowledge of the things of God by the power of his spirit, and sought not after signs and wonders, and when the spirit rested upon them seemed to produce no visible demonstration.* (Ibid)

George A. Smith knew there was a significant change in convert's visionary and ecstatic experience following the death of Joseph Smith. Direct and personal experience with angels and God gave way to revelation described as inspirational manifestations. As discussed above, in every case involving entheogen use in early Mormonism, a change in mental and emotional state was apparent to non-intoxicated observers both inside and outside the Church. That cessation of observable symptomology associated with post-Joseph Smith spiritual experience and the lack of visions and ecstasies reported by his successors provide persuasive evidence that Joseph Smith made use of entheogens. Even more noticeable are the many contemporary reports of entheogen-facilitated visions and ecstasies echoing those of Joseph Smith and early of Mormon converts.

The cessation of convert and leadership visionary and ecstatic experience following the death of Joseph Smith may partly inform the observation of Sterling Professor of Humanities at Yale University, Harold Bloom (2007) when he observed, "*I am puzzled by the current Salt Lake City hierarchy. If there is any spiritual continuity between [Joseph] Smith and Gordon B. Hinckley [a Prophet and Utah successor to Joseph Smith], I am unable to see it. No disrespect is intended by that observation.*" If "placebo sacraments" replaced those infused with entheogens in early Mormonism, the spiritual discontinuity between Joseph Smith and his successors noted by Hard Bloom is readily accounted for and easily explainable.

Entheogenic successors

More than any other American religion, Mormonism has spawned several forays into entheogenic sacraments. We start with Joseph Smith's grandson, Frederick G. Smith.

Frederick M. Smith

The evidence reviewed above that Joseph Smith kept a Native American peyote stone as a sacred possession, attempted to locate a colony in peyote country, and intended to offer his followers peyote in the temple to facilitate their experience of God puts us in a better position to now to address a question we raised early in the paper. Like his grandfather Joseph Smith, Frederick M. Smith (1875-1946) manifested a precocious openness to entheogens, particularly peyote. As shown by Emma's letters and oral transmission of information to her children and grandchildren about the entheogenic-potent herbs jimson (datura) and lobelia, information about entheogens was passed on from Joseph Smith Jr's generation not through his Church but within his family. Joseph's family was also heirs to his hand-tooled seer stone in a peyote button. After his death, the stone remained in possession of his widow Emma, who passed it on to her second husband, Lewis Bidamon. The stone eventually came into the possession of Lewis's illegitimate son Charles Bidamon.

Frederick G. Smith, born in 1874, is likely to have seen the stone as a child and would have known it by reputation at the least. As the stone passed beyond the Smith family and eventually to collector Wilford C. Wood, any oral lore passed along with the stone within the Smith family failed to be transmitted with it further, and the stone was known only as one of Joseph Smith's seer stones, with no other information about its provenance or significance. However, just because the stone's representational significance was unknown to those who later sold and bought, it does not mean this significance was unknown to the Smith family.

Joseph Smith family's cross-generational legacy of a peyote stone and oral traditions about entheogenic herbs, and possibly about the stone itself, makes it unsurprising that Frederick M. Smith would have been exceptionally open to using entheogens, including peyote. Joseph Smith's revelations were the "bed-rock" of Mormonism and Frederick "*wanted to understand the [revelatory] process*," a subject he explored in *The Higher Powers of Man* (1918), with an entire chapter devoted "*to the wonders of peyote*" (Tommasini, 1997, p. 83). In this work, Frederick discussed the usefulness of peyote as an aid to spiritual development, reverberating his previous entheogenic experiences, experiences "*he did not dare to chronicle*" (Tommasini, 1997, p. 83). Frederick wrote, "*Ecstasy has played an important role in human affairs, particularly the religious, and it is scarcely stating the matter fairly to hold that it is always associated with the pathological. Ecstasy is the central experience of religious experience usually associated with mysticism*" (Smith, 1918).

Frederick learned "*the rituals and powers of peyote*" while pursuing his PhD in psychology. When Frederick visited Texas on vacation, "*he observed Native American Indians who ate [peyote] ... [and] Catholic converts, who [drank it as a tea] for communion*" (Tommasini, 1997, p. 83). Frederick believed the use of peyote in a spiritual setting was not a violation either of the spirit or the letter of his grandfather, Joseph Smith's 1833 dietary revelation known as the "word of wisdom" (Smith, 1833, pp. 207-208). "*Frederick did not believe that peyote was technically, a drug. To him it was a natural substance, an ancient means to tap one's inner power derived from hallucinogenic cactus [as Frederick put it, is] 'neither injurious nor habit-forming'*" (Tommasini, 1997, p. 83).

Frederick introduced peyote to Virgil Tomson (1896-1989), an American composer who played a significant role in creating an "American Sound" in classical music. Smith gave Virgil "*five bumpy little buttons less than an inch across and hard as wood and suggested that he chew them up before he went to bed*" (Ibid). Virgil described his experience: "*The effect, full visions complete in color and texture as a stage set, began slowly to appear before my closed or open eyes. Then came more rapidly ... Each one, moreover, had a meaning [and] could have been published with a title; and their symbolisms or subjects ... constituted a view of life not only picturesque and vast, but just as clearly all mine and all true*" (Tommasini, 1997, p. 84).

Virgil introduced S. Foster Damon, an academic and poet specializing in the mystic William Black, and "*who reported on the similarity of Blake's art to Peyote visions*" (Piper, 2016). Frederick, Virgil, Damon, and others belonged to a "Harvard psychedelic circle" who were engaged in the exploration of peyote spirituality (Piper, 2016). Damon was profoundly affected by his peyote experiences and subsequently penned articles titled, *The Evidence for Literal Transmutation* and *Symbols of Alchemy* (Ibid). In *Symbols of Alchemy*, Damon (1922) argues that "*To the alchemists, 'Gold,' the most perfect in the metalline world, stood for Man, the perfect product of creation*" and "*'to make gold,' actually meant to make (or materialize) a human being*" (p. 79). Damon also discussed "*The Elixir of Life*" stating it was called such "*because of the way it [by a chemical* *process] manifested itself ... since by its means, the afterworld could be reached*." Further, "*each alchemist used a new term [for the Elixir] every time he could think of one*" (p. 81). Damon argued that Alchemists kept their secret by means of symbols and "*frankly confessed that they deliberately confused their symbols*" because it "*was a matter of life and death for these men to keep their secret: one hint, and they with all their colleagues would have been massacred*" (Ibid, 79, emphasis added). We have argued that Joseph Smith's intentionally obscured entheogen for the same reason.

Frederick Smith represents a rare confluence of many factors discussed in this paper. He was the patrilineal grandson of Joseph Smith, the prophet of the Reorganized Mormon church (1915-1946), a classically trained psychologist, and his doctoral thesis extensively discussed and advocated for using the entheogen peyote in religious settings. And if Frederick Smith's engagement with psychedelics and the "Harvard psychedelic circle" (Piper, 2016) reverberated in family traditions of his grandfather Joseph Smith's engagement with psychedelics, then Joseph Smith may himself have exerted an indirect but positive influence on the unfolding of psychedelic culture in the United States. One might think such was the case since the next "Harvard psychedelic circle" included Timothy Leary, Ram Dass, Huston Smith, and Andrew Weil who played a significant role ushering in a "New Age" for America (Lattin, 2011).

Contemporary scripture in the Community of Christ establishes Joseph Smith's original, historic goal of universal prophethood as one of the faith's immediate priorities. Revelations issued by Community of Christ prophet presidents Grant McMurray and Stephen Veazey and accepted by the Church into its *Doctrine and Covenants* (Community of Christ, 2007) who proclaim that participants in the Community of Christ are called "to be a prophetic people" and to "live prophetically" (Section 162:2c, 8c; 164:1). With its heritage of two early prophets who used and promoted entheogens as a potent means for living out this age-old vision, the Community of Christ is perhaps uniquely positioned among restorationist and liberal Christian denominations to leverage entheogens to become "a prophetic people" as Joseph Smith envisioned.

Oto Church of the First-Born and the Native American Church (NAC)

The Mormon-Indian-peyote syncretisms began in 1914 with the incorporation the Oto Church of the First-Born, the predecessor to the Native American Church (Rigal-Cellard, 1995). According to Weston La Barre (1938), early Plains Indian peyote "*rites diffuse[ed] from the Kiowa-Comanche ... [to] the Oto Church of the First-born ... and its successor, the Native American Church*." In their Churches, the Oto met to see the "*faces of their dead relatives*" and the Osage met "*to see the face of Jesus*" (Ibid).

The Oto Church of the First-born was found by Jonathan Koshiway (La Barre, 1938), the first Native American syncretism to seek legal incorporation. Koshiway was a missionary for the Reorganized Church of Jesus Christ of Latter Day Saint, now the Community of Christ and later "met with Kiowa and Arapaho to found the Native American Church" (Rigal-Cellard, 2004).

The Oto Church of the Firstborn likely represents Koshiway familiarity with the Mormon concept of the "Church of the Firstborn," and its visionary nature as described in Mormon scripture. Joseph Smith (1844) explained that Mormon's who were faithful and obtained the ordinances,

> "*have the privilege of receiving the mysteries of the kingdom of heaven, to have the heavens opened unto them, to commune with the general assembly and Church of the Firstborn, and to enjoy the communion and presence of God the Father, and Jesus the mediator of the new covenant*" (pp. 101-102; also see Collier, 1977).

Probably, Koshiway viewed peyote as the key to commune with the heavenly Church described by Joseph Smith.

The Peyote Way Church of God

The next Mormon-Native American-peyote syncretism, The Peyote Way Church of God (PWCG), was founded by Reverend Immanuel Pardeahtan Trujillo in 1979 and is based in Willcox, Arizona (Rigal-Cellard, 2004). In 1948, before founding the PWCG, Rev. Trujillo (50% San Carlos Apache) joined the NAC. However, Trujillo became dissatisfied with the NAC because it limits membership and peyote sacrament to "genuine Natives" who can prove at least 25% American Indian ancestry, and their spouses regardless of race. Trujillo's objection arose when, "*William Russell, Apache Roadman for the NAC. Rev. Russell and Rev. Eugene Yoakum. .. [taught] Trujillo about the Spirit Walk and instilled in him the non-racist nature of the Holy Sacrament Peyote*" (Peyote Way Church of God, n.d.).

Preferring not to limit peyote sacraments to Native Americans, Trujillo left the NAC in 1966. The PWCG "*strictly adheres to the creeds of the L.D.S. Church*" (Rigal-Cellard, 2004). According to Rigal-Cellard, "*Anne Zapf, the President of the Church from 1985 to 1993, became a Mormon while in college and helped Trujillo settle the Church and … a fairly high number of Natives of the region belong to the L.D.S. Church*" (Ibid). Shields (1982, p. 221) goes further stating the PWCG descends from Joseph Smith's Mormonism. The PWCG believes that Joseph Smith's "Word of Wisdom" (D&C 89) provides for their peyote sacrament (Murphy, 1994a, 1994b). Furthermore, the bylaws of the PWCG published in 1981 permit it to: "*To grow, obtain, steward, protect and defend the Holy Psychedelic Sacrament of Peyote and its religious use; and to regulate the distribution of this Holy Psychedelic Sacrament to other members of this and other churches that use a psychedelic as their Holy Sacrament.*"

In its mission to offer peyote sacraments to non-Native Americans, the PWCG ran into legal difficulties. In 1991, one leader, Brother Bill Stites, was arrested by federal officers for felony possession of peyote found in his car (Rigal-Cellard, 2004). The legal challenges to the NAC offering peyote sacraments to non-Native Americans faced by the PWCG would bleed into the legal woes of the next Mormon-Native American-peyote syncretism, the Oklevueha NAC (ONAC).

James Warren "Flaming Eagle" Mooney

James Warren Mooney, a former Mormon, is the founder of the controversial ONAC that openly provides peyote ceremonies for people without Native American descent. Mooney reports being told in 1988 by Oklevueha Chief and Medicine Woman Little Dove he was a descendant of both Osceola, the Seminole Indian chief, and the famed ethnologist James Mooney (1861-1921); these genealogical attributions would become a center of controversy.

James Warren Mooney, then a Mormon and successful businessman, was given to understand that he was called to carry Native American plant medicine to non-Indians, the particulars of which he was instructed to decide for himself (L. B. Buford, personal communication, May 6, 2019). In 1994, after a lengthy period of training with various Native American medicine people including Guadalupe Rio de la Cruz, a Huichol Medicine woman, Mooney, conducted NAC peyote sacrament ceremonies without regard to race. In 1997, Mooney founded the ONAC and in 2000 was excommunicated from the Church of Jesus Christ of Latterday Saints.

In 2001, Mooney's home and new Church was raided by local law enforcement officials. In these places of worship, according to Mooney, they seized peyote amounting to over thirty pounds, representing about 10,000 dried peyote buttons. Mooney and his wife, arraigned on charges of "*a dozen counts of drug trafficking and one count of racketeering,*" faced life in prison (Gehrke, 2001). The State of Utah contended that Mooney was not covered by the Federal Religious Peyote Exemption (21 C.F.R. § 1307.3) because he was not of Native American descent, nor a member of a federally recognized tribe. The trial resulted in James' and his wife Linda's conviction on multiple felony counts related to what was alleged to be a criminal enterprise based on distributing peyote within the context of their religious services. In 2003, the Mooney's appealed the trial court's decision to the Utah Supreme Court who: "*Reverse[d] the trial court's decision … the federal regulation does not restrict the exemption to members of federally recognized tribes. We therefore rule that the exemption is available to all members of the Native American Church*" (State of Utah, 2004).

Following this decision, the Utah District Attorney attempted to convince the federal government to prosecute James and Linda on similar charges related to peyote sacrament. The question in the government's case against James Mooney was his claimed Native American descent. Unexpectedly, government-certified genetic testing revealed Mooney's ethnicity: 58% European, 35% Native American, and 9% Sub-Saharan African. (Certificate of Ancestry, 2005). After 6 months of investigation by United States Federal Attorneys and Federal Investigators, the case against James Mooney resolved when the Mooneys entered into a plea agreement. In conversation with one of the authors, Mooney believes that ONAC worldwide membership top well over 10,000.

Conclusions

In this paper, we have reviewed the historical and psychopharmacological data that Joseph Smith employed entheogens in religious ordinances, facilitating many early Mormon visions and ecstasies. Gaining proficiency over time, Smith dealt with troublesome entheogen-related symptomology and "difficult trips" by encoding them, along with entheogenic visions and ecstasies, in his published teachings and revelations. The reproduction of biblical prophetic and apostolic experience and the antidepressant effects of entheogens in early Mormonism contributes to an understanding of Joseph Smith's charisma and the spectacular rise of his Church - it continues to do so if only in story. If organized religion is to relevant in our post-modern, Internet-informed, and ecopsychologically sensitive world, it must come to grips with what cognitive and neuroscience have to say about religious experience as natural phenomena and entheogens as near-universal facilitators of that experience.

Acknowledgements: The authors would like to thank Cindy Winkelman for her work in completing and formatting references, and Michael Winkelman for his tireless assistance and mentoring. They would also like to thank historian Don Bradley who provided extensive research on Joseph Smith's first vision, possible origins of the peyote stone, activities as an herbalist, and entheogenic Freemasonry; and his son Don Bradley Jr. who offered insight into Joseph Smith Sr.'s possible identification of entheogens with the Bible's "forbidden fruit" and "tree of life." They would also like to acknowledge the vast amount of historical data covering the Joseph Smith period that has been published as electronic transcriptions and photocopies of original documents by the Church of Jesus Christ of Latter-day Saints and the historical documents published by the Community of Christ. To their credit, these two Churches have placed on the Internet, both appealing and troublesome aspects of their foundation, making the combined collection an invaluable resource to researchers in religious studies. Collectively, these publications are well situated to provide valuable insights into religions with visionary and ecstatic origins, and whose historical data is relatively sparse.

Conflict of interest: The authors have no conflicting interest in writing and publishing this paper.

Abstract

Did hallucinogens facilitate Joseph Smith's visions & those of early Mormon converts? In his 1975 book, *Hearts Made Glad*, Lamar Petersen carefully documented the use of intoxicants by Joseph Smith and early converts to the LDS Church. While mostly interested in the consumption of various fermented and distilled alcohols, Petersen also noted strange behaviors associated with the sacramental use of what seemed to outside observers to be medicated wine. It appears that soon after the Church was organized in New York and later in Ohio, members partook of wine in sacrament meetings which occasioned visionary states and strange behaviors not typically associated with alcohol consumption or intoxication. It is my thesis that beginning at a young age, Joseph Smith experimented with psychedelic plants and that many of Joseph Smith revelations and much of his behavior can be attributed to the use of psychedelics. Following Joseph Smith's death, the pragmatic Brigham Young had no interest in psychedelic material, or was unaware of its use, and hence it did not become a part of Utah Mormonism. However, James Strang and Fredrick M. Smith (Joseph Smith's grandson and president of the RLDS Church) perpetuated the use of psychedelics in their branches of Joseph Smith's original movement. The use of psychedelics by the Strangites and the RLDS Church could not be sustained.

Introduction

According to the official web site of the LDS Church, in the spring of 1820, Joseph Smith offered a simple prayer that set into motion a series of events leading to the restoration of the true Church and the truth about life's greatest questions.[1] But for many early LDS coverts, learning about truth was a second rank endeavor. Instead, seeking for a personal visionary experience was primary. According to LDS scholar, Richard Bushman, early Mormon converts were "seekers" whose

> ... greatest hunger was for spiritual gifts like dreams, visions, tongues, miracles, and spiritual raptures.[2]

These early Church members sought direct experience with God and believed that Joseph Smith had the power to grant their desires. Confidence in their Prophet was not misplaced. Between 1829 and 1836, under the supervision of Joseph Smith, many early Mormon converts enjoyed heavenly visions and spiritual raptures. While the nature of these visions are a matter of debate, there is no doubt as to the amazing number of visions experienced by Joseph Smith and early converts during these seven years.

However, after Joseph's death in 1844, the great visionary period of Church history came to an end.[3] The only vision recorded in Church of Jesus Christ of LDS scripture (D&C 138) is that of Joseph F. Smith dated October 3, 1918. Since 1918, there has be no visionary experience recorded by any of the subsequent presidents of the LDS Church. Interestingly, the vast majority of Mormons living today believe that Joseph Smith-like visionary and revelatory experience continues amongst the living "General Authorities" of the Church, but in secret. However, an Apostle of the LDS Church admitted in 1985 that he had never had such an experience and he was unaware of anyone living who had. (In person interview of an LDS Church Apostle by the author)

So stark was the dearth of visionary experience that in 1864, twenty years after Joseph Smith's death, members would ask Mormon Apostle George A. Smith,

> ...why it is that we do not see more angels, have more visions, that we do not see greater and more manifestations of power?[4]

The mystery seems to center around Joseph Smith himself. According to Richard Bushman, it was Joseph Smith himself that connected converts to heaven by some power that he possessed, a power that remains a mystery to this day.[5]

Indeed, after the death of Joseph Smith in 1844, the only vision recorded in LDS history is that of Joseph F. Smith dated October 3, 1918. (D&C 138)

But is Joseph Smith's spiritual power to connect converts with heaven really beyond our ability to investigate and understand? Over the last 50 years Joseph Smith-like spiritual power has come under examination by an ever-increasing number of anthropologists, religious historians, ethno botanists and ethno mycologists. It now appears that spiritual power comparable to that of Joseph Smith can be acquired in the course of consuming visionary plants, mushrooms and cactus. Otherwise known as psychedelics and hallucinogens, when these visionary materials are taken in a religious setting, they are often referred to as entheogens. An entheogen is any substance, such as a plant or drug, taken to occasion a heavenly vision or spiritual rapture.[6] Entheogens can induce visions during an altered state of waking consciousness and out-of-body and near death experiences.

How important are entheogens to the world's great religions? In 2000, Robert C. Fuller, a leading historian and interpreter of American religious life wrote that the use of entheogens

> ... is one of the most mysterious and important subjects in all religious history. Entheogens have figured prominently in the mystical practice of some of the world's greatest civilizations. They have been widely employed in shamanic society and their use continues today throughout the world. They alter consciousness in such a profound way, that ... their effects can range from states resembling psychosis to what are perhaps the ultimate human experiences, union with god or revelations of other mystical realities.[7]

The psychobiology of non-pharmacologic and pharmacological induced altered states of consciousness is now a matter of scientific research. Michael Winkelman writes,

> Vision-inducing plants ("hallucinogens") are important in many societies, evoking powerful emotional, psychological, cognitive, religious, spiritual, therapeutic and political reactions. These substances' psychophysiological properties shape cross-cultural similarities in patterns of use and experiences, while political factors shape their cultural desirability. Neurological studies illustrate that common effects are based in intervention in serotonergic neurotransmission. Effects upon neural, sensory, emotional, and cognitive processes stimulate integrative information processing, justifying a new term- "psychointegrators." Psychointegrators disinhibit sensory and emotional processes. They stimulate systemic integration of brain information-processing functions, enhancing integration of limbic system self and emotional dynamics with neocortical processes. Their therapeutic applications are reviewed from perspectives of cross-cultural and clinical studies. (Abstract from: Psychointegrators: Multidisciplinary Perspectives on the Therapeutic Effects of Hallucinogens, Michael Winkelman. Arizona State University Tempe, AZ)

Just how legitimate are visions and raptures occasioned by entheogens? Religious historian Huston Smith wrote that the use of entheogenic material is able to occasion an "experience that is indistinguishable from, if not identical with" those of religious mystics.[8] For instance, in an article published in Life Magazine May 13th 1957, R. Gordon Wasson, the "father of ethnomycology", reported the discovery of a divine mushroom that could easily occasion visions and ecstasies. Wasson wrote,

> On the night of June 29, 1955... I shared with a family of Indians a celebration of "holy communion" where "divine" mushrooms where first adored and then consumed.[9]

Wasson then reports,

> Now I am seeing for the first time, seeing direct, without the intervention of mortal eyes ... vistas beyond the horizons of this life, to travel backwards and forwards in time, to enter other planes of existence, even to know God.[10]

But Wasson's experience isn't an isolated example of psychedelics ability to reproduce a transpersonal, religious experience. In 1961, Huston Smith ingested peyote cactus and made a similar report.

> I noted mounting tension in my body that turned into tremors in my legs ... I [began] experiencing ... the clear, unbroken Light ... I was now seeing ... with the force of the sun, in comparison with which everyday experience reveals only flickering shadows in a dim cavern ... [I saw] worlds within worlds.[11]

In a 2000 essay, Huston explains that through an entheogen, he experience the ultimate reality.

> The personal word is this: I was initiated to the entheogens through Timothy Leary and psilocybin in his home in Newton on New Year's Day, 1961. The day didn't change my worldview, for the Great Chain of Being had already moved to the center of my convictions through thirty years of jnanic work with the great religions. What the day accomplished, you will not be surprised to hear, was to enable me for the first time to experience the respective levels of the Chain, all the way to its top. The dominant effects of the experience were two: awe (which I had known conceptually as the distinctive religious emotion but had never before experienced so intensely) and certainty. There was no doubting that the Reality I experienced was ultimate. That conviction has remained.[11b]

From the 1950's to present, an increasingly large volume of data has been assembled in the quest to understand the use of entheogens in important religious and mystery traditions. Hebrew, Mexico, Central and South America, India, China, Siberia, Europe, and ancient Greece, Christian and Alchemical mythic-religious systems often refer to visionary plants or fungi.[15] The result has been a maturing theory of entheogens and the origins of religion. In September 2006, Michael S. Hoffman summarized what is now believed by many to be the relationship between religion and entheogens.[12]

> The entheogen theory of religion holds that the main origin and ongoing wellspring of religion is visionary plants ... [such as] Peyote ... *Datura* ... and *Amanita muscaria* mushrooms. Visionary plants have been commonly used around the world throughout the history of religion and culture,[13] including the various forms of Western Esotericism.[14]

More recently, in the premier issue of Time and Mind, Benny Shannon, Professor of psychology at the Hebrew University of Jerusalem (Israel).

> In his book *Poisons Sacrés, Ivresses Divines* [sacred poisons, divine intoxication] (which, to my knowledge, has not been translated into English), Philippe de Félice (1970 [1936]) reviews various cultures throughout the world and notes the use of psychotropic substances in them. The use of such substances, most of which fall in our contemporary Western culture under the label "drug," has in many traditions been considered sacred. Indeed, de Félice points out that in many religions, both in the old world and in the new, the use of such substances was (and often still is) central. The substances, or the plants from which they were produced, were deemed holy and at times even divine. De Félice puts forward the hypothesis that the use of psychotropic substances is deeply embedded in human culture and intrinsically intertwined with what he characterizes as the most basic human instinct - the search for transcendence. Thus, he proposes, the use of psychotropic substances is at the root of perhaps all religions. (Time and Mind Volume 1, Issue 1, March 2008, pp. 51-74 - http://www.psychointegrator.com/down/biblical_entheogens.pdf)

In the patients to successfully treat mental disorders and the anxiety associated with the diagnosis of cancer. The Fox News Networks broadcast a segment about the psychedelic substance "Psilocybin" and asked the question "Can this dangerous party drug help extend the life of terminally ill patients?" The cases of two patients were reviewed followed by a short statement of the principle investigator, Dr. Charles Grob professor of Psychiatry at Harbor UCLA Medical Center. Dr. Grob makes this additional comments

> It might even facilitate a powerful psychispiritual or even mystical experience which does appear to have a therapeutic impact.

If entheogens can shed light on some of the world's most important religions, including possibly early Christianity, is it possible that they may also shed light on the rise of Mormonism, America's most successful religion? In order to address this question, it seems reasonable to consider the motive, opportunity and evidence to suggest that Joseph Smith employed entheogens to occasion heavenly visions and spiritual raptures.

Motive to Administer Entheogens

What would motivate Joseph Smith to use entheogens? One possible answer is that without entheogens, most visions and raptures come only after years of disciplined meditation or severe physical austerity. Ake Hultkranz, retired professor of comparative religion[16] explains that the popularity of entheogens ... is partly due to the fact that visions are rendered easily accessible, and fasting, isolation, and self-torture[17] are unnecessary.

Terence McKenna, speaker and philosopher, is widely known to be experienced in the use of psychedelics and the meditative arts. McKenna believes that meditative and other spiritual practices were developed as tools to enhance and guide the psychedelic experience. His views in a small discussion group are summarized (with minor editing) as follows:

> Q. Are you against meditation in favor of the psychedelics experience? A: If by meditation you mean lying down or sitting up and close your eyes, I do that a lot and I like it but would never confuse it with the psychedelic enterprise. I think they are completely different realms of human activity. With meditation, you don't hallucinate. [Some may] say you do, but they aren't very convincing. [And when you fail to hallucinate with meditation] the monks rush over and explain that you are doing it wrong.

> Q. Do you think you have the same revelatory experience with meditation? A: I really don't. All these spiritual techniques are not substitutions for the psychedelic experience but trade-offs. I think that all of these techniques ... work incredibly well in the presence of psychedelics leading me to suppose that what these are tools that were developed in the Paleolithic world of psychedelic magic and all we have now is all these tools but we don't have the original engine that drove them. I am very bored by spiritual practice unless I've taken a psychedelic; then mantric chanting is beyond the power of mind to encompass or describe. [Psychedelics] seems to be a general functional enhancement [of spiritual techniques]. Acoustical driving (drumming) is also a tried and true tradition. It's not about the exclusivity of methods but the combinations of method. What you want to do is beat your drum while sitting in yum, yum [position] while stoned on "x", while at the holy mount, while the astrological configuration is correct and then line it all up and push it through, that's the way to do it.

While most will not achieve a "revelatory experience" with meditation alone, there are techniques which may facilitate such experiences in a limited number of devotes. For instance, William Buhlman has developed several out-of-body meditation techniques that has been successful in some cases. Techniques developed by Stephen LaBarge are able to produce lucid dreams. In lucid dreaming, the dreamer becomes conscious during the dream and in some cases may be enveloped in a religious epiphany. Joseph Smith is known to have used a seer stone to see buried treasure and to "translate" the Book of Mormon. The technique is called scrying and as discussed by Clay L. Chandler, is another technique to enter revelatory realms.

However, these techniques are relatively unreliable for most seekers and often takes years of practice to produce meaningful revelatory results. It is becoming apparent that meditation, fasting and religious ceremony may not be primary causes of visionary states and spiritual raptures but instead in many cases play a supportive role for the use of entheogens. Michael Hoffman notes

> Meditation, shamanic drumming, and liturgical ritual were developed as activities to do in the plant-induced [visionary] state, not as methods of inducing the [visionary] state in the first place.[18]

In other words, if Joseph Smith employed entheogens, he met the requirement to place himself and early Mormon converts in the express lane to spiritual powers without the need for years of meditation, repetitive religious ritual or severe physical austerities.

Access and Training to Administer Entheogens

How available were entheogens to Joseph Smith. In 1998, Richard Evans Schultes, former director of the Botanical Museum of Harvard University and the "father of ethnobotany" identified three culturally important entheogens available in the area Joseph lived and traveled: *Datura* plant, *Amanita muscaria* mushroom and peyote cactus.

Culturally Significant Major Entheogens Accessable from Where Joseph Smith Lived According to Richard Evans Schultes

Peyote Cactus

Amanita muscaria
(Fly Amanita)

Datura
(Angel's Trumpet)

C. Jess Groesbeck, who studied with a Huichol Indian Shaman, has shown that the model of Joseph Smith as a shamanic personality is a comprehensible way to understand and embrace Joseph's life and work.

Groesbeck defines shaman:

> Mircea Eliade, a great historian of religion said, "This is the particular type of medicine man, holy man or healer who through the controlled use of trance or ecstasy communicates directly with the spirits and realities of the other world for the benefit of his community." Ake Hulkrantz stated that a shaman is a social functionary who with the help of guardian spirits obtained ecstasy in order to create rapport with the supernatural world on behalf of the individual or group members and his power comes from direct experience. Other people such as priests and other official healers and representatives often do this through technology or indirectly through various structures or systems or mythological structures, whereas the shaman, if he is truly in that character has the direct experiences and in fact becomes the creator, as we shall see, and synthesizer of the symbolic experiences, these otherworldly experiences for a new system of religion or belief or understanding or healing...
>
> They ultimately have an experience through ecstasy, through trance, through dissociation. They then go to the other world and have contact usually with animals, an animal of some kind. And that animal then will give them their personal powers. Through this experience, many times, they will go through dismemberment experiences where they themselves will see in vision themselves being dismembered and then put back together. Later, when they have these personal powers, they often have the powers of telepathy, psychokinesis, precognition, the ability to interpret dreams and then also to see. They are often seers and they use sacred objects such as stones by which to visualize. And then they have helping spirits or agents who come to them and who work with them.[19]

It is possible that AmerIndian Shaman were mentors for Joseph Smith in his use of entheogens. There is reason to believe that Joseph Smith was familiar with Indian chief. Charles M. Larson writes that a fragment of the Egyptian papyrus purchased by Joseph Smith in 1835

> was given to an Indian chief as a token of respect. (Charles M. Larson, ... By His Own Hand Upon Papyrus: A new look at the Joseph Smith Papyri, Institute for Religious Research, Grand Rapids Michigan, 1992, p. 78, note 230 states, "This was the basis for the article in the February, 1968 Improvement Ears, p. 40-A through 40- G...")

Mircea Elliade, during his early work, was not convinced that the use of psychedelics was an important aspect of indigenous shamanic work. However, just before he died, he reversed his position recognizing the nearly universal use of psychedelics by indigenous shaman.

Michael Cole, the Charles J. MacCurdy professor emeritus of Anthropology at Yale University and curator emeritus of the Division of Anthropology at the school's Peabody Museum of Natural History also believes that Joseph Smith is best described as a Shaman. Speaking of Joseph Smith, Cole explains

> This extraordinary man, who put together a religion - probably with many falsities in it, falsehoods, so forth, to begin with - eventually came to believe in it so much that he really bought his own story and made it believable to other people. In this respect, he's a lot like a shaman in anthropology: these extraordinary religious practitioners in places like Siberia, North America among the Eskimo, the Inuit, who start out probably in their profession as almost like magicians doing magic. (PBS Interview, May 16th 2006)

Algonquin Indian shamans inhabiting the region from the Atlantic seaboard running north through eastern and central Canada and south to the Ohio River are known to have used both *Datura* plant and *Amanita muscaria* mushroom in their religious ceremonies.[20] Since Jess Groesbeck has shown that many aspects of Joseph Smith's visionary career is consistent with Amerindian shamanism, it is possible that Joseph Smith was mentored by an Algonquin shaman.

John Heinerman has demonstrated Joseph Smith's interest in Thomsonian herbal medicine. Thomsonian medicine was inspired by early American root doctors using magical plants to occasion cures. According to Catherine Yronwode, "root doctoring" is an admixture of the hoodoo magical practices of African-American slaves mingled with the botanical knowledge of the Amerindian medicine man.[21] Root doctors are known to have used the visionary *Datura* plant in their magical practices.[22] A possible mentor for Joseph Smith in the use of *Datura* was Black Pete. Black Pete, an African-American was called a revelator and a chief suggesting that he was also a root doctor. Black Pete was initially from Pennsylvania and in 1825 may have met the young Joseph Smith digging for buried treasure. After leaving Pennsylvania, Black Pete became one of the earliest converts in Kirtland Ohio joining the Church in early 1831. Black Pete was present during the Kirtland visionary period of early 1831 when the strange manifestations likely associated with *Datura* plant ingestion were particular pronounced.

D. Michael Quinn and Lance S. Owens have shown that Joseph Smith incorporated elements of ceremonial magic and alchemy imported from Europe.[23] Alchemists are believed to have employed the visionary *Amanita muscaria* mushroom in their occult practices[24] and Lance Owens identifies a possible alchemical mentor for Joseph Smith by the name of Dr. Luman Walter.[25] Quinn writes,

> As previously discussed, folk magic and the occult involved training, practice, and inner "gifts" to be an adept. Academic magic required occult texts, hundreds of which were available in English by the 1800s (see Ch. 1, and above). Folk magic's universal source of instruction was the occult's oral tradition which summarized centuries-old writings for all classes of people. Many people gained occult knowledge from both directions. Aside from verbal transmission of occult knowledge, some adepts also furnished practical training to interested persons. (Quinn. Early Mormonism. 116)

There is evidence that Joseph's mother, Lucy Mack Smith, used seer stones, and Joseph may have gained most of his knowledge regarding their use from her, but Quinn also points to the probability that Joseph had one or more occult mentors, Luman Walters being primary among them. (Clay L. Chandler, Scrying for the Lord:

Magic, Mysticism, and the Origins of the Book of Mormon. Dialogue: A Journal of Mormon Thought, Vol. 36, No. 4, Winter 2003. p. 43
http://www.dialoguejournal.com/wpcontent/uploads/sbi/articles/Dialogue_V36N04_63.pdf)

Joseph Smith may have also been in contact with Amerindian shaman familiar with the use of the visionary Peyote cactus. The Peyote cactus grows in an extensive area surrounding the middle and lower Rio Grande River. Amerindian Peyote cults spread northeast from these areas to the plains states many years after Joseph Smith died.

However, an ancient Amerindian trade route led from the Peyote fields through a major trade center to the Northeast where Joseph Smith resided.[26] It is very probable that Peyote was transported along this route and found its way into Joseph Smith's hands because at the time of his death, Joseph possessed a seer stone shaped in the form of the visionary Peyote cactus button.

Use of Entheogens to Discover and Translate the Gold Plates

It has been reported that Joseph Smith was typically intoxicated while discovering and translating the Book of Mormon. According to Lu B. Cake, Joseph Smith was intoxicated during his "vision of Moroni" dated September 21, 1823. LeMar Petersen notes,

> At what age and in what capacity Vermont-born Joseph, Jr. arose to prominence is a moot point among his biographers. Mormon historians have dated his fame from the vision of the Gods in the Sacred Grove in 1820.* Others, less credulous, have insisted that Joseph's notoriety sprang from participation in necromantic arts accompanied by frequent tilts of the bottle. Joseph's self-admitted foibles were not charitably viewed by critics who were willing to place the worst possible interpretation on them. I. Woodbridge Riley, in a Yale University thesis for which he was awarded the Doctor of Philosophy degree in 1902, accused:
>
>> "What took place between the first and second visions was described by Joseph as the 'weakness of youth, foolish errors, divers temptations and gratifications of appetites offensive in the sight of God.' Stripped of verbiage this means, for one thing, - drunkenness."[12]
>> (http://archive.org/download/founderofmormoni00rilerich/founderofmormoni00rilerich.pdf)
>
> A lurid monograph certain not to win a degree for its author was Lu B. Cake's *Peepstone Joe Exposed* (http://archive.org/download/peepstonejoepeck00cake/peepstonejoepeck00cake.pdf) which appeared just prior to Riley's psychological study. Adding an introduction to the presentation of a manuscript by Reed Peck (an officer in the Danite band whose testimony helped put Joseph in Liberty jail in 1838), Cake wrote:
>
>> "September 21, 1823 Joe got drunk, swore, lied and swindled, contrary to revelation. Train up a child in the way he should *not* go and when he is eighteen years old like Joe Smith, he will not depart from it. Yet Joe claims that while in bed this drunken September 21st, an angel came to him, told him the history of the ancient inhabitants of America was engraven on gold plates and hidden in a hill between Manchester and Palmyra, in western New York. Whether it was angel, or alcohol, that gave Joe inspiration is the question; for although drunk on September 21st, yet on September 22nd he claims that he found the plates in the place to which he was directed."[14] Inasmuch as Peck had not referred to Joseph's inebriety in the MS, it may be that Cake obtained his information by direct revelation. (LeMar Petersen, Hearts Made Glad: *Charges of Intemperance Against Joseph Smith the Mormon Prophet*. 1975. Self-Published. Salt Lake City. 44-45)

Intoxication can explain Joseph Smith's visionary experiences but not intoxication with alcohol. Having worked in an Emergency Department for over 30 years, I have never seen an intoxicated patient who was actively hallucinating unless there was pre-existing alcohol induced central nervous system damage. If we accept that Joseph Smith was intoxicated and link that intoxication to visions, the only intoxicant class capable of doing that is psychedelics such as *Amanita muscaria* mushroom, *Datura* and Mescaline containing cactus.

It is possible that Joseph was intoxicated with a hallucinogen during the visionary experiences surrounding his September 1923 vision and later enabling him to see sentences in spiritual light while excluding natural light using a seer stone placed in the hat. Joseph Smith was intoxicated while translating the Book of Mormon. LeMar Petersen notes:

> One of Emma Hale Smith's cousins, Levi Lewis, son of Reverend Nathaniel Lewis of the Methodist Church, made affidavit that while Joseph was in Harmony, Pennsylvania he "saw him intoxicated three different times while he was composing the Book of Mormon."[55]
>
> Another who reported that Joseph drank too much liquor while translating was Martin Harris, first scribe for the modern scripture. When the wine goes in, strange things come out.[64] But after censure from the High Council at Kirtland he amended the charge to "this thing occurred previous to the translation of the Book." Shalemanasseh (one of Martin's spiritual names in the Doctrine and Covenants 82:11) then confessed that his mind was darkened, and that he had said many things inadvertently, calculated to wound the feelings of his brethren, and promised to do better.[57] (LeMar Petersen, *Hearts Made Glad: Charges of Intemperance Against Joseph Smith the Mormon Prophet*. 1975. Self-Published. Salt Lake City. 65-66)

This is not to suggest that Joseph Smith wasn't frequently intoxicated on alcohol. The evidence is clear that he was. However, alcohol is an excellent vehicle to administer both *Amanita* and *Datura*. That Joseph Smith was knowledgable about the use of medicated alcohol is found in the *Book of Mormon*. LeMar Petersen notes,

> The scene with the Missouri jailors is reminiscent of a scene concerning the wicked Lamanites in the first edition of the Book of Mormon:
>
> > "And many times did they atempt to administer of their wine to the Nephites, that they might destroy them with poison or with drunkenness. But behold, the Nephites were not slow to remember the Lord their God, in this their times of affliction. They could not be taken in their snares; yea, they would not partake of their wine; yea, they would not take of wine, save they had firstly given to some of the Lamanite prisoners. And they were thus cautious, that no poison should be administered among them; for if their wine would poison a Lamanite, it would also poison a Nephite; and thus they did try all their liquors.[16]
>
> In Mormon belief the Lamanites of the Book of Mormon were the ancestors of the American Indian. It is fortunate the Lamanite wine-tasters of old were spared a sampling of the potent brew prepared for their Missouri descendants. This heady recipe for Indian firewater was given by "Teddy Blue" Abbott (born 1860) in *We Pointed Them North*:
>
> > "You take one barrel of Missouri River water, and two gallons of alcohol. Then you add two ounces of strychnine to make them crazy - because strychnine is the greatest stimulant in the world - and three plugs of tobacco to make them sick - an Indian wouldn't figure it was whisky unless it made him sick - and five bars of soap to give it a bead, and half a pound of red pepper, and then you put in some sagebrush and boil it until it's brown. Strain into a barrel, and you've got your Indian whisky; that one bottle calls for one buffalo robe and when the Indian got drunk it was two robes." (LeMar Petersen, *Hearts Made Glad: Charges of Intemperance Against Joseph Smith the Mormon Prophet*. 1975. Self-Published. Salt Lake City. 150-151)

Intoxication and visionary experience is hinted at in the Book of Mormon. A more through discussion of the "bitterness" or bitter taste of psychedelics and the "opening" of one's eyes was tangentially expressed by LeMar Petersen.

> Though Joseph's philosophy was only partially hedonistic a good case for sin could be made from certain Book of Mormon passages. The patriarch Lehi explained to his son Jacob that sin was necessary and desirable in the Garden of Eden, otherwise Adam and Eve
>
> > "would have had no children; wherefore they would have remained in a state of innocence, having no joy, for they knew no misery, doing no good, for they knew no sin."
>
> Moral: To do good, one must sin; transgression is essential. This precept may well be the key to Joseph Smith's ambivalence in drink habits and in those areas of behavior generally defined as moralistic. He often affirmed that "what many people call sin is not sin," and "there must needs be opposition in all things." The most oft-quoted phrase in Mormonism, next to "The glory of God is Intelligence," is "Adam fell that man might be, and man is that he might have joy." In Mormon belief the fall was upward.[34]
>
> In Joseph's scriptures Adam blessed God
>
> > "for because of my transgression [eating from the tree of knowledge] my eyes are opened, and in this life I shall have joy," and Eve, the abettor, seconded, "were it not for our transgression we never should have had seed, and never should have known good and evil."
>
> The Lord explained to Adam,
>
> > "Inasmuch as thy children are conceived in sin, even so when they begin to grow up, sin conceiveth in their hearts, and they taste the bitter, that they may know to prize the good."
>
> And though conceived in sin
>
> > "every spirit of man was innocent in the beginning; and God having redeemed man from the fall, men became again, in their infant state, innocent before God."
>
> Nevertheless, "since man had fallen he could not merit anything of himself." The difficulty of reconciling such passages with God's first command in Genesis to "be fruitful and multiply, and replenish the earth" seemed not to disturb the modern Revelator.[35]
>
> Did not God countermand his own word in,
>
> > "But of the tree of the knowledge of good and evil, thou shalt not eat of it: for in the day thou eatest thereof thou shalt surely die?"
>
> (LeMar Petersen, Hearts Made Glad: *Charges of Intemperance Against Joseph Smith the Mormon Prophet*. 1975. Self-Published. Salt Lake City. 158-159)

The connection between eating, the initial bitter taste and eventual sweetness of joy while apparently metaphorical is also an excellent description of the effects of ingesting psychedelics many of which are bitter but eventually envelop the inbiber in spiritual raputures of love. How this might relate to Joseph Smith Senior's dreams and Joseph Smith Junior's "tree of life" will be discussed below.

Opportunity to Administer Entheogens

Is there evidence to suggest that Joseph Smith gifted new converts with visionary experience by adding a visionary plant such as *Datura* to sacramental wine? According to LaMar Petersen in his 1975 book, *Hearts Made Glad* the answer is probably yes.[27] Petersen noted a correlation in early Mormonism between the ingestion of sacramental wine and visionary experience. In the very first conference of the Church in June 1830 at Fayette, New York,

Joseph Smith recorded

> ... we partook together of the emblems of the body and blood of our Lord Jesus Christ ... many of our members ... had the heavens opened to their view, [and beheld Jesus Christ].[28]

Heavenly manifestations occurred in a March 18th 1833 sacrament meeting held in Kirtland Ohio under the direction of Joseph Smith.

> Bro Joseph ... promise[d] that the pure in heart that were present should see a heavenly vision ... after which the bread and wine was distributed by Bro Joseph after which many of the brethren saw a heavenly vision of the savior and concourses of angels.[29]

In the afternoon of March 27th 1833, Ebenezer Robinson reported that after the administration of the bread and wine

> Frederick G. Williams bore record that a holy angel of God came and sat between him and Joseph Smith, Senior.[30]

A meeting in which visions were occasioned by the application of anointing oil, which can also be laced with entheogenic material[31] occurred on January 21, 1836. Joseph Smith was anointed first and in turn he anointed several of the Brethren. Joseph reported that after the anointing,

> The heavens were opened upon us and I beheld the celestial kingdom of God, and the glory thereof, whether in the body or out I cannot tell ... Joseph said that many of the brethren "saw glorious visions also.[32]

Pentecost for Richard Bushman, Joseph Smith, Rough Stone Rolling

> Thursday January 21 1836 A new kind of washing; one for the whole body was instituted, following OT practices. Joseph's journal: "We attended to the ordinance of washing our bodies in pure water. We also perfumed our bodies and our heads, in the name of the Lord" Oliver C. gave a fuller description of the W and A. No spiritual, otherworldly things mentioned.
>
> When the brethren met the following Thursday, they added an anointing with oil. Joseph and six other men attended to this. They poured the oil on the heads and then rubbed their hands over his anointed face and head. In Exodus it called for calumus and myrrh and sweet cinnamon. Cinnamon was all these poor saints could afford to mix with the oil. Hmmm?
>
> After Joseph's anointing he wrote, "the heavens opened upon us and I beheld the celestial kingdom of God and the glory thereof, whether in the body or out I cannot tell." "Streets of gold" "Alvin" etc. All through the night Joseph had visions. "Many of the other brethren saw visions also." JS. After the presidency Joseph anointed the bishops of Kirtland and Clay County with their counselors. Edward Partridge wrote "a number of them saw visions and others were blessed with outpouring of the Holy Ghost. The vision of heaven was opened to these also, some of them saw the face of the Saviour and others were ministered unto by holy angels." At 1am they sang a song and went home.

> The next day no one could concentrate on school. They wanted to talk over "the glorious scenes that transpired on the preceding evening." That evening the twelve and the seventy underwent same. Following the ordinances "toungs, fell upon us in mighty pow[e]r, angels mingled their voices with ours, while their presence was in our midst, and unseasing prasis swelled our bosoms for the space of half an hour." Joseph said "the spirit and visions attended me through the night."
>
> Six days later they did anointings for high priests and then quorum. Through January and February, the brethren read Hebrew by day, and washed, anointed, and prayed, and beheld visions by night. He went home weary.
>
> Some quorums did not comply with everything they were asked to do one Sat. early in Feb. They were not standing and speaking when they had a spiritual experience. Hyrum and Oliver went to request them to observe order but they said that "they had a teacher of their own and did not wish to be troubled by others." Joseph said, "This quorem lost the[e]ir blessing in a great measure." A "cloud of darkness" filled the elders' room, their minutes reported, while the more careful quorums "enjoyed a great flow of the holy spirit" that was "like fire in their bones."
>
> At the temple dedication on Mar 27 they did all the tedious sustainings, then the dedicatory prayer. Some said they saw angels etc. But the congregation did NOT see the face of God. The level of spiritual manifestations did not equal the outpourings of January and Feb. Bushman says. Mar 29 washing of feet and sacramental wine. Holy Spirit, prophecying and giving glory all night in temple Mar 30 about 300 people joined them in the temple. More tubs more towels, bread and wine. Prophecying and speaking in tongues. Exhausted after the all night session the presidency retired but the rest of the brethren remained, "exhorting, prophecying, speaking in tongues" until 5am. A few skeptics wondered if the brethren had become drunk on sacramental wine, but according to JS journal the nonstop Tues and Wed meetings were, finally, the endowment. (What they wanted to happen at the dedication) The next Sunday about 1000 people attended (they must have heard about that great wine huh?) the morning service. To their surprise (J and O?) the spiritual experiences in the temple were not over. Behind a veil J and O saw the Savior standing on the breastwork of the pulpit. Bushman says, What could this staggering experience have meant to J and O? (They had too much sacramental wine maybe) Joseph seemed to be stilled by the event. They saw Moses ELIAS and Elijah but after this no mention of the experience in D&C during J lifetime. The Book of Abraham's weirdo stuff started to happen after this two month high. No wonder it is such a messed up thing.

On March 30, 1836 during the dedication week of the Kirtland temple the *Millennial Star* reported that nearly five hundred brethren gathered in expectation of a spiritual Pentecost.

> The bread and wine were then brought in … The Savior made His appearance to some, while angels ministered to others.[33]

Charles L. Walker recorded that when the brethren had

> … partaken of the Lord's supper, namely a piece of bread as big as your double fist and half a pint of wine in the temple … the Holy Ghost descend upon the heads of those present like cloven tongues of fire.[34]

Following consumption of sacramental bread and wine on the afternoon of April 3rd 1836, Joseph Smith and Oliver Cowdery retired to the pulpit where a series of visions were opened to them including the appearance of Jesus Christ, Moses, Elias and Elijah.[35]

Then in a meeting on May 1st 1836, Ebenezer Robinson[36] remembered

> … when we partook of consecrated bread and wine … some testified of having the visions of heaven opened to their view.[37]

Can untainted wine and pure anointing oil have occasioned heavenly visions or spiritual raptures of early Church converts? The answer is probably not. Alcohol related hallucinations only occur after years of abuse and abrupt withdrawal. Therefore visions associated with the ingestion of wine argue strongly for the surreptitious inclusion of an entheogen such as the visionary *Datura* plant.

Evidence of Datura Use

What evidence is there that the plant *Datura* occasioned early Mormon convert visions rather than hypnosis, mass hysteria or spontaneous religious experience? *Datura* has been shown to be over 80 percent effective in creating a visionary experience whereas hypnosis is much less reliable, probably less than 10 percent. An even smaller percentage, likely less than 1 percent, will experience spontaneous heavenly visions. *Datura* would not only account for the high percentage of early Church converts having visionary experience following the ingestion of sacramental wine, but may also explain the accompanying untamed thoughts and behaviors that attended early Mormon sacrament meetings.

Lamar Petersen noted that the drinking of sacramental wine in the early days of the Church occasioned "unusual spiritual manifestations" of such a shocking nature they "impaired the image of the young Church among sober people."[38] In early 1831, sacrament meetings held at the Kirkland Ohio farm of Isaac Morley produced both visions and scandalous behavior. A Kirtland Ohio schoolteacher, Jesse Moss observed

> They partook of the Lords supper at night with darkened windows and excluded from the room all but their own till they got through and then opened the doors and called the outsiders in to witness a scene far exceeding the wildest scene ever exhibited among the Methodists.[39]

What were the wild scenes associated with early Mormon administration of sacramental wine?

Reporter	Undisciplined Scenes
George A. Smith[40]	- Unnatural distortions - Extravagant and wild ideas
David Whitmer[41]	- Wielded the sword of Laban as expertly as a light dragoon - Acted like an Indian in the act of scalping - Slid on the floor with the rapidity of a serpent, sailing in boats to preach to the Lamanites.
Parley P. Pratt[42]	- Swoons - Unseemly gestures - Cramps - Falling into ecstasies
Joseph Smith[43]	- Insanity - Bound hand and foot in chains as immovable as a stick of timber - Getting on the stumps of trees and shouting Pursuing balls flying in the air and jumping of a cliff.

As shown in the table above, George A. Smith reported that members in Kirtland manifested unnatural distortions and extravagant and wild ideas.[44] David Whitmer said that members wielded the sword of Laban as expertly as a light dragoon, behaved like Indians in the act of scalping, slid on the floor with the rapidity of a serpent, sailed in boats to preach to the Lamanites.[45] Parley P. Pratt reported swoons, unseemly gestures, cramps and falling into ecstasies.[46] Joseph Smith himself noted manifestations of insanity, members becoming immovable as though bound hand and foot.[47]

Joseph Smith reportedly was not present at these Kirtland meetings and disavowed the manifestations as being of a lying spirit. However, Joseph Smith's own first vision was attended by similar strange thoughts and behaviors. Eldon Watson who harmonized Joseph's nine accounts of the first vision notes the following aberrations from normal thinking and bodily function.[48]

A Harmony: Excerpted

For Full Accounts Click Here

Arranged by Elden J. Watson with References

All of these signs and symptoms described below can be produced by hallucinogens, especially *Amanita muscaria* Mushroom and *Datura* Species!

Incapacitation (An effect of anticholinergic)

- **1839** I had scarcely done so, when immediately I was [seized] upon by some power which entirely overcame me … But exerting all my powers to call upon God to deliver me out of the power of this enemy which had seized upon me, and at the very moment when I was ready to sink into despair and abandon myself to destruction, not to an imaginary ruin but to the power of some actual being from the unseen world who had such marvelous power as I had never before felt in any being … It [the light] no sooner appeared than I found myself delivered from the enemy which held me bound.

Normal Vision Impared, Darkened (Dilation of pupils, blurry vision, marked decrease in vision)

- **1839** I had scarcely done so, when immediately I was [seized] upon by some power which entirely overcame me. Thick darkness gathered around me and it seemed to me for a time as if I were doomed to sudden destruction.
- **1840** At first, he was severely tempted by the powers of darkness, which endeavored to overcome him;
- **1842B** At first, he was severely tempted by the powers of darkness, which endeavoured to overcome him.

Anxiety and Strange Visuals (Early paranoia and unorganized visual distortions/hallucinations)

- **1842B** The adversary benighted his mind with doubts, and brought to his soul all kinds of improper pictures and tried to hinder him in his efforts and the accomplishment of his goal.

Tongue Felt Swollen & Stuck to Roof of Mouth (Anticholinergic drying effect on mouth)

- **1835** My tongue seemed to be swoolen in my mouth, so that I could not utter
- **1839** and [had] such an astonishing influence over me as to bind my tongue so that I could not speak.
- **1844** his tongue was closet cleaveh to his roof - could utter not a word,

He heard strange sounds (Auditory Hallucinations)

- **1835** I heard a noise behind me like some one walking towards me: I strove again to pray, but could not; the noise of walking seemed to draw nearer; I sprang upon my feet and looked round, but saw no person, or thing that was calculated to produce the noise of walking.

Withdrawl from Physical Sensations (As Physical Incapitation Increases, Thinking Switches from External Sensations to Inner Realities)

- **1842B** However, the overflowing mercy of God came to buoy him up, and gave new impulse and momentum to his dwindling strength. Soon the dark clouds disappeared, and light and peace filled his troubled heart.
- **1840** but he continued to seek for deliverance, until darkness gave way from his mind … When [the light] first came upon him, it produced **a peculiar sensation throughout his whole system; and immediately, his mind was caught away, from the natural objects with which he was surrounded**; and he was enwapped in a heavenly vision,
- **1842A** while fervently engaged in supplication my mind was taken away from the objects with which I was surrounded, and I was enwrapped in a heavenly vision
- **1842B** At this sacred moment his mind was caught away from the natural objects with which he was surrounded, and he was enwrapped in a heavenly vision,

Brilliant light (Extremely Common with Hallucinogens)

- **1832** a pillar of ~~fire~~ light above the brightness of the sun at noon day come down from above and rested upon me.
- **1835** A pillar of fire appeared above my head; which presently rested down upon me, and filled me with unspeakable joy.
- **1839** Just at this moment of great alarm, I saw a pillar [of] light exactly over my head, above the brightness of the sun, which descended ~~gracefully~~ gradually untill it fell upon me.
- **1840** he at length, saw a very bright and glorious light in the heavens above; which, at first, seemed to be a considerable distance. He continued praying, while the light appeared to be gradually descending towards him; and as it drew nearer, it increased in brightness and magnitude, so that, by the time that it reached the tops of the trees, the whole wilderness, for some distance around was illuminated in a most glorious and brilliant manner. He expected to have seen the leaves and boughs of the trees consumed, as soon as the light came in contact with them; but perceiving that it did not produce that effect, he was encouraged with the hope of being able to endure its presence. It continued descending slowly, until it rested upon the earth, and he was enveloped in the midst of it.
- **1842A** surrounded with a brilliant light which eclipsed the sun at noon-day.
- **1843** Directly I saw a light,
- **1844** -saw a fire toward heaven came near and nearer;
- **1850** While he was thus engaged, he was surrounded by a brilliant light.

Psychodramatic Theophany (The sought after psychedelic experience)

- **1832** and I was filled with the spirit of god and the [lord] opened the heavens upon me
- content well known. See Accounts of First Vision

Return of Physical Sensations (Waning of the hallucinatory experience and gradual return of normal physiological functioning).

- **1839** When I came to myself again I found myself lying on [my] back looking up into Heaven... When the light had departed I had no strength, but soon recovering in some degree,
- **1840** after which, the vision withdrew,
- **1842B** after which, the vision withdrew,
- **1843** The vision then vanished, and when I came to myself, I was sprawling on my back ...and it was some time before my strength returned.
- **1844** I endeavored to arise but felt uncommon feeble
- **1850** after which the vision withdrew

Afterglow of Hallucinatory Experience (Antidepressant Effect of Psychedelics)

- **1832** and my Soul was filled with love and for many days I could rejoice with **great Joy** and the Lord was with me
- **1840** leaving his mind in a state of **calmness and peace, indescribable**.
- **1842B** leaving his mind in a state of calmness and peace indescribable.
- **1850** leaving his mind in a state of calmness and peace.

Notes

Joseph's tongue would not function, he heard strange sounds and sprang to his feet but saw nothing, he was seized upon and could not move, his vision was severely impaired, he saw all kinds of "improper pictures", he believed he was going to be destroyed, he felt a peculiar sensation course through his entire body, he lost consciousness and awoke to find himself sprawling on his back and was unable to get up for some time.

Joseph Smith personified these strange manifestations as the actions of a being from the unseen world. This is consistent with Joseph's analysis of the bizarre manifestations in 1831 Kirtland Ohio as being the responsibility of a lying spirit. However, Joseph would contradict this view in 1843 when he explained that evil spirits can neither manipulate the physical world nor occasion strange physical manifestations. Joseph explained to apparently worried Church members that if such a being was encountered and attempted to physically interact, nothing at all would be felt.[49]

Rather than the devil being responsible for the peculiar manifestations attending the first vision and early Church convert visions, it is much more likely that *Datura* plant was involved.

Clinical Effects of Datura	**Correlates with LDS Visions**
Hallucinations (83%)	Visions
Pupil Dilatation	Blindness
Dry mucus membranes	Dry mouth, can't speak
Vasomotor instability	Facial color changes (initially flushed, then white as blood pressure falls)
Delirium, paranoia (central stimulation)	Unfounded fears, feeling of impending death, acting like or preaching to Indians, crawling, wallowing, chasing balls flying through the air.
Muscle abnormalities (jerks, myclonic movements, choreoathetosis)	Facial and body contortions, feeling bound
Unconsciousness (central depression)	Coma
Onset: 1-4 hours Duration: 24-48 hours	Experiences lasted hours to days.

As noted above, *Datura* is over 80% reliable in occasioning hallucinations and visions. It also causes pupil dilatation and near blindness, dry mucus membranes making it difficult to speak; vasomotor instability with the face initially turning red then white as blood pressure falls; delirium including acting out inner visions and paranoid ideation; abnormal muscle movements including jerks and contortions and finally unconsciousness. Symptom onset is usually less than an hour and can continue for as long as two days.

The *Independent Messenger* published in Worcester, Massachusetts reported on May 27th 1831 that

> Some [Church members] lie in trances a day or two and visit the unknown regions in the meantime; some are taken with a fit of terrible shaking which they say is the power of the Holy Ghost.[50]

In an early June 1831 Kirtland sacrament meeting, Joseph Smith alluded to possible mass visions and outright promised Lyman Wight that he would see Christ that day. Bushman explains what happened next:

> Wight turned stiff and white, exclaiming that he had indeed viewed the Savior ... Joseph himself said, "I now see God, and Jesus Christ" ... Then Harvey Whitlock ... turn as black as Lyman was white ... his fingers were set like claws. He went around the room and showed his hands and tried to speak, his eyes were the shape of ovals "O's" ... [Then] Leman Copley, who weighed over two hundred pounds, somersaulted in the air and fell on his back over a bench ... [Similar behavior was manifested by] people all day and the greater part of the night.[51]

In the *Independent Gazetter* published in Taunton, Massachusetts on January 11, 1833 it was reported that "in a few hours at a single meeting" there would be

> ... shoutings, wailing, fallings, contortions, trances, visions, speaking in unknown tongues and prophesying.[52]

John W. Gunnison who interviewed Church elders present during the 1836 Kirtland Pentecost reported that wine was administered ...

> ... that had been consecrated, and declared by the Prophet to be harmless and not intoxicating. This... produced unheard of effects, if we may credit the witnesses of these proceedings. Visions, tongues, trances, wallowings on the ground, shoutings, weeping, and laughing, the outpouring of prophecies... these, and other fantastic things, were among 'the signs following' at Kirtland.'[53]

Joseph Smith's standard response was to attribute foul manifestations to the adversary while the heavenly manifestations were attributed to God. But a more reasonable explanation may be that the visionary effects of *Datura* plant are frequently accompanied by rather unnerving physical and psychological side effects.

Some witnesses of these events came to the conclusion that the sacrament had been laced with a drug. On January 6, 1831, a letter to the editor in the Palmyra Reflector[54] accused Joseph Smith of legerdemain. Legerdemain means the practice of using "psychology, misdirection and natural choreography in accomplishing a magical effect."[55] In other words, Joseph Smith was being accused of using the sacrament as misdirection for the surreptitious administration of a visionary substance. In 1843, Henry Caswell wrote of "a pretended sacrament" associated with manifestations of power in early LDS meetings.[56]

After witnessing several sacrament meetings in Kirtland Ohio, Jesse Moss "became fully satisfied the wine was medicated" and one night attempted to steal a bottle but was caught. Immediately after his attempt was discovered, Moss made a public statement about how with drugged wine "angels could be manufactured & strange wonders made to appear in the night".[57]

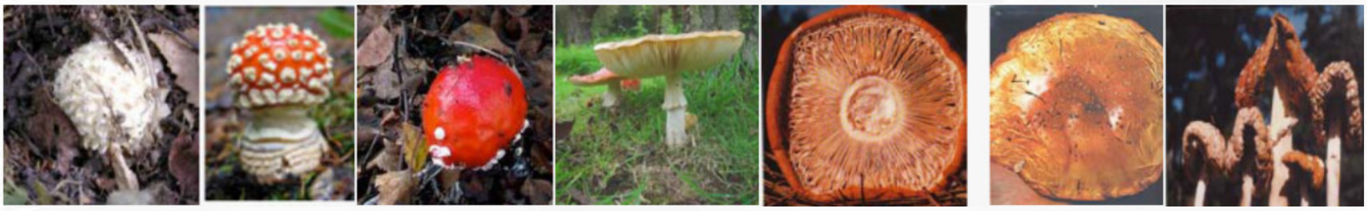
A member of the Church by the last name of McWhithey was reportedly present during the 1836 Kirtland temple dedication week. Obviously disgruntled, McWhitney complained that the wine consumed was actually "mixed liquor" and that "the Mormon leaders intended to get the audience under [its] influence" so that visions experienced were believed to be of "the Lord's doings."[58]

The connection of wine with fits of psychotic thinking and strange physical manifestations attending heavenly visions and spiritual raptures argues strongly in favor of the covert inclusion of the visionary *Datura* plant in the sacramental meal and anointing oil administered by Joseph Smith.

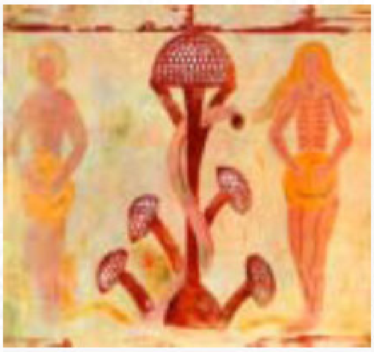
Amanita muscaria Mushroom

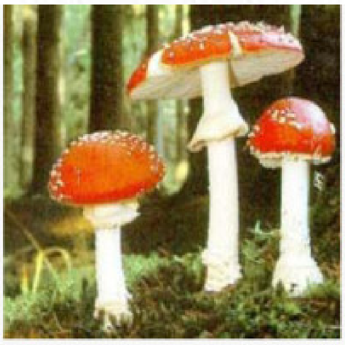
What about Joseph Smith's own use of entheogens? As noted, the psychotic thinking and peculiar physical manifestations attending Joseph's first vision are compatible with *Datura* plant ingestion. But another entheogen most likely was the intoxicant involved.

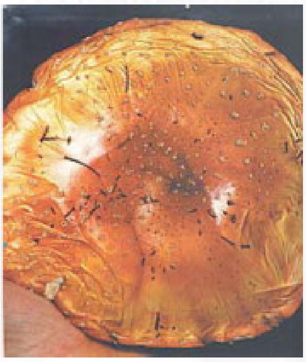
The *Amanita muscaria* mushroom may be one of man's oldest entheogens. According to Dan Merker, an academic with a background in religious history, an entheogenic laced sacrament existed in a Judaeo-Christian context.[59] Clark Heinrich suggests there is evidence to believe the *Amanita muscaria* mushroom may have played a role, along with ergot fungus related to LSD, in occasioning the visions reported by Old Testament prophets as well as being employed in some early Christian Eucharist celebrations.[60] However, these entheogens were not administered openly, but covertly within a more benign substance such as wine and anointing oil. To maintain secrecy, descriptions of *Amanita muscaria* mushroom use were cloaked in allegory and metaphor. (Listen to Clark Heinrich discuss the *Amanita* Mushroom.)

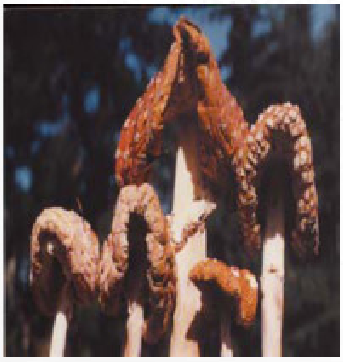


The *Amanita muscaria* mushroom, because of its changing form; its symbiotic relationship with pines, oaks and birch trees; and its profound visionary effect makes itself amenable to mystical personification and simile. A few examples of the *Amanita muscaria* mushroom in various stages of life underneath its host trees are shown above. In its newborn state, it takes on the appearance of a small dazzling white stone or particle; then a woolly lamb, a constellation of sun, moon and stars, a brilliantly colored ground fruit; a winged bird adorned with a string of pearls around its neck; a sun disk radiating light in all directions; a gold plate upon which is found strange writing and a serpent hanging on a pole. According to those who have consumed this fruit, the visionary state it produces occasions an endowment of divine knowledge and celestial love.









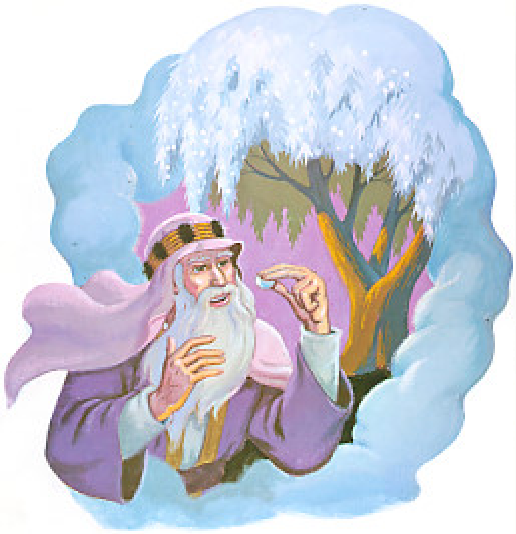
This 13th century Christian fresco from France shows an *Amanita muscaria* mushroom as the tree of knowledge with Adam on the left and Eve on the right. Notice the tree's umbrella shaped branches bearing white particles analogous to the veil remnants on the caps of three *Amanita muscaria* mushrooms shown to its right. Also, in the Christian fresco, the gold plates covering Adam and Eve's nakedness match the golden color of an aged *Amanita muscaria* mushroom. Finally, the snake hanging on a pole in the Christian fresco corresponds to a dying *Amanita muscaria* mushroom that also has an appearance of a snake hanging on a pole.

What is remarkable about this early Christian pictographic simile of the *Amanita muscaria* mushroom is its resemblance to the dreams of Joseph Smith Sr. and the early visionary experiences of Joseph Smith Jr. In 1802, Joseph Sr. gathered and crystallized more than $3000 worth of ginseng to sell in China.[61] Ginseng, although not a major entheogen, was "attributed with secret and magical powers".[62] The ability to crystallize ginseng shows that Joseph Sr. was able to work with psychoactive material, changing it into a stable, storable form that could be administered at a later time.

In 1811, Joseph Sr. reportedly had two dreams that are very suggestive of the *Amanita muscaria* mushroom. In the first dream, a spirit led Joseph Sr. to a box on the ground containing an entheogenic material. Of the box, the spirit said

> the contents of which, if you eat thereof, will make you wise, and give unto you wisdom and understanding.[63]

In the next dream, Joseph Sr. was led to a tree whose "branches spread themselves somewhat like an umbrella" and released "particles ... of dazzling whiteness" which fell to the ground. When he partook of fruit lying on the ground, he experienced something "delicious beyond description". Then Joseph Sr. with his family "got down upon [their] knees, and scooped [the fruit] up, eating it by double handfuls".[64]



In 1830, Joseph Smith Jr. published his own version of his father's entheogen related dreams. In an early chapter in the *Book of Mormon* those who held onto the rod of iron ultimately "fell down and partook of the fruit of the tree" which represented the love of God. It is not a far stretch to think that a single entheogen is being described in these three related dreams.

The points where the Smith dreams appear to represent the *Amanita muscaria* mushroom are ...

1. the umbrella shape of the tree branches,
2. the brilliant white particles on the branches, appearing to fall to the ground arguably appearing as small brilliant white stones
3. the fruit that must be gathered from the ground, not plucked from the branches of the tree as would be expected
4. fruit that can either be eaten fresh or dried and stored for later consumption
5. magical fruit able to occasion visions and raptures bestowing divine wisdom and heavenly love.

The *Amanita muscaria* mushroom not only fits the images depicted in the Smith dreams, it also has the capacity to reproduce the early visionary experiences reported by Joseph Smith. The 1832 account of the first vision, written 12 years from when it reportedly occurred, had undoubtedly already undergone significant revision. The core event was arguably an experience of physical heaviness, visual darkness, an awe-inspiring light from above, a voice out of heaven, an experience with the unfathomable Godhead and feelings of unspeakable joy.[65]

Contemporary visionary experience occasioned by entheogens show remarkable similarity to that of Joseph Smith. For instance, a few years ago, after ingesting the *Amanita muscaria* mushroom in the context of a Christian sacramental meal, Clark Heinrich reports a Joseph Smith-like first vision. Heinrich writes

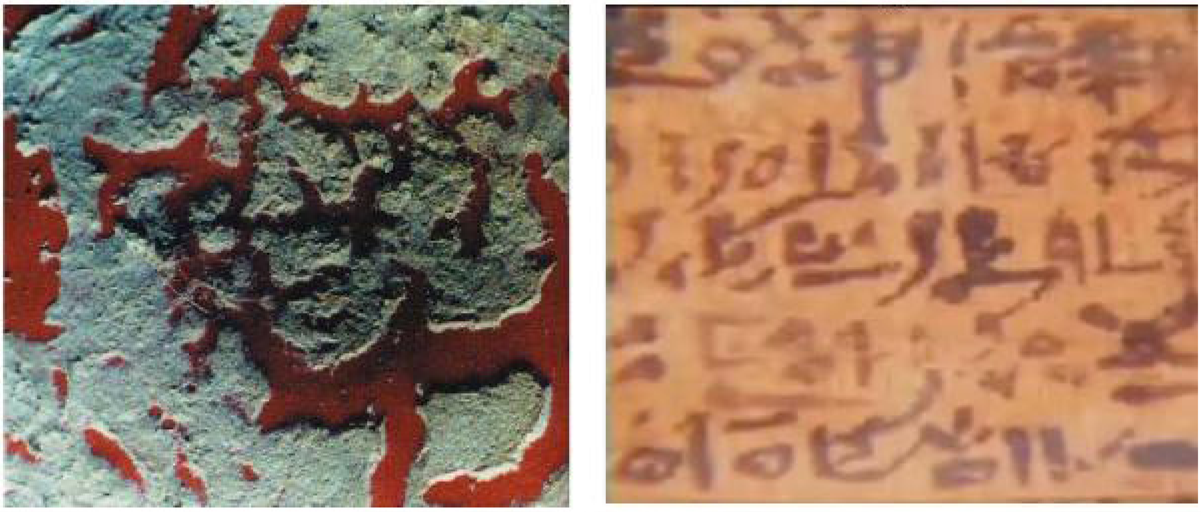
> I felt like I weighed thousands of pounds and could no longer sit up ... in the midst of a great darkness and a great silence, the heavens opened above my head. In an instant I was flooded with light from above, light of the utmost whiteness and splendor that quickly dissolved everything in its glory. The bliss I had experienced prior to this new revelation now paled to insignificance in an immensity of light that was also the purest love. As the truth of the situation dawned on me the word "FATHER" resounded in this heaven of light and I was taken up and absorbed by the unspeakable Godhead.

The similarity of Heinrich's vision to that of Joseph Smith's is remarkable including immobility, darkness, light appearing from above, a voice out of heaven, an experience with the Godhead and the feeling of indescribable joy. James Arthur reports that the *Amanita muscaria* "mushroom is also a symbiotic with the Birch tree, the trees which were in the Sacred Grove".[66]

On another occasion in which *Amanita muscaria* mushroom was ingested in a sacramental setting, Heinrich reported an experience reminiscent of the February 16, 1832 joint vision of Joseph Smith and Sydney Rigdon. This singular vision was manifested as they read from the *Book of John*. Similarly, Heinrich and a friend partook of the sacred *Amanita muscaria* sacrament, opened the *Bible* to the *Book of John* and reported having a singular spiritual experience.

I picked up a *Bible* from the bookshelf, opened to the *Book of John*, and started reading aloud. What I had before considered ridiculously partisan prose and poetry (fiction really) was now revealed in a whole new light. It became for us an [*Amanita muscaria*] initiation document, speaking the living truth directly to us through the mists of the centuries, uncovering layer after layer of meaning artfully hidden in the text. We understood it all; all the references, all the metaphors, all the hidden wisdom ... It was as though God had manifested from the book and was addressing us directly. And we couldn't have been happier.[67]

The *Amanita muscaria* mushroom may also have played a role in Joseph's account of the *Book of Mormon*'s origin. This sacred mushroom appears in the autumn of each year coinciding with Joseph's annual visits to the Hill Cumorah. Importantly, Joseph told his wife and his mother that he hid the gold plates in an oak and birch tree. Interestingly, *Amanita muscaria* mushroom grows in symbiotic relationship with both trees. The sacred mushroom is born underneath a tree as a small "pure brilliant white stone"[68] which is then transformed into a woolly lamb, then a brilliant red fruit; a constellation of sun, moon and stars and finally a gold plate upon which appears to be written strange hieroglyphs. On the left is a freshly picked shiny gold *Amanita muscaria* mushroom in its potent entheogenic form. The photo on the right is a collection of dried gold *Amanita muscaria* mushrooms that retain their entheogenic potency for up to a year.[69]



Amanita muscaria

Book of Abraham Papyrus

A comparison of a photo of an *Amanita muscaria* mushroom on the left with hieroglyphics from an Egyptian manuscript shows remarkable similarity. *Amanita muscaria* may also have occasioned Joseph's interest in translating. In a recent study conducted in Britain, ingestion of *Amanita muscaria* mushroom stirred a member of the test group to spontaneously translate an unknown language.

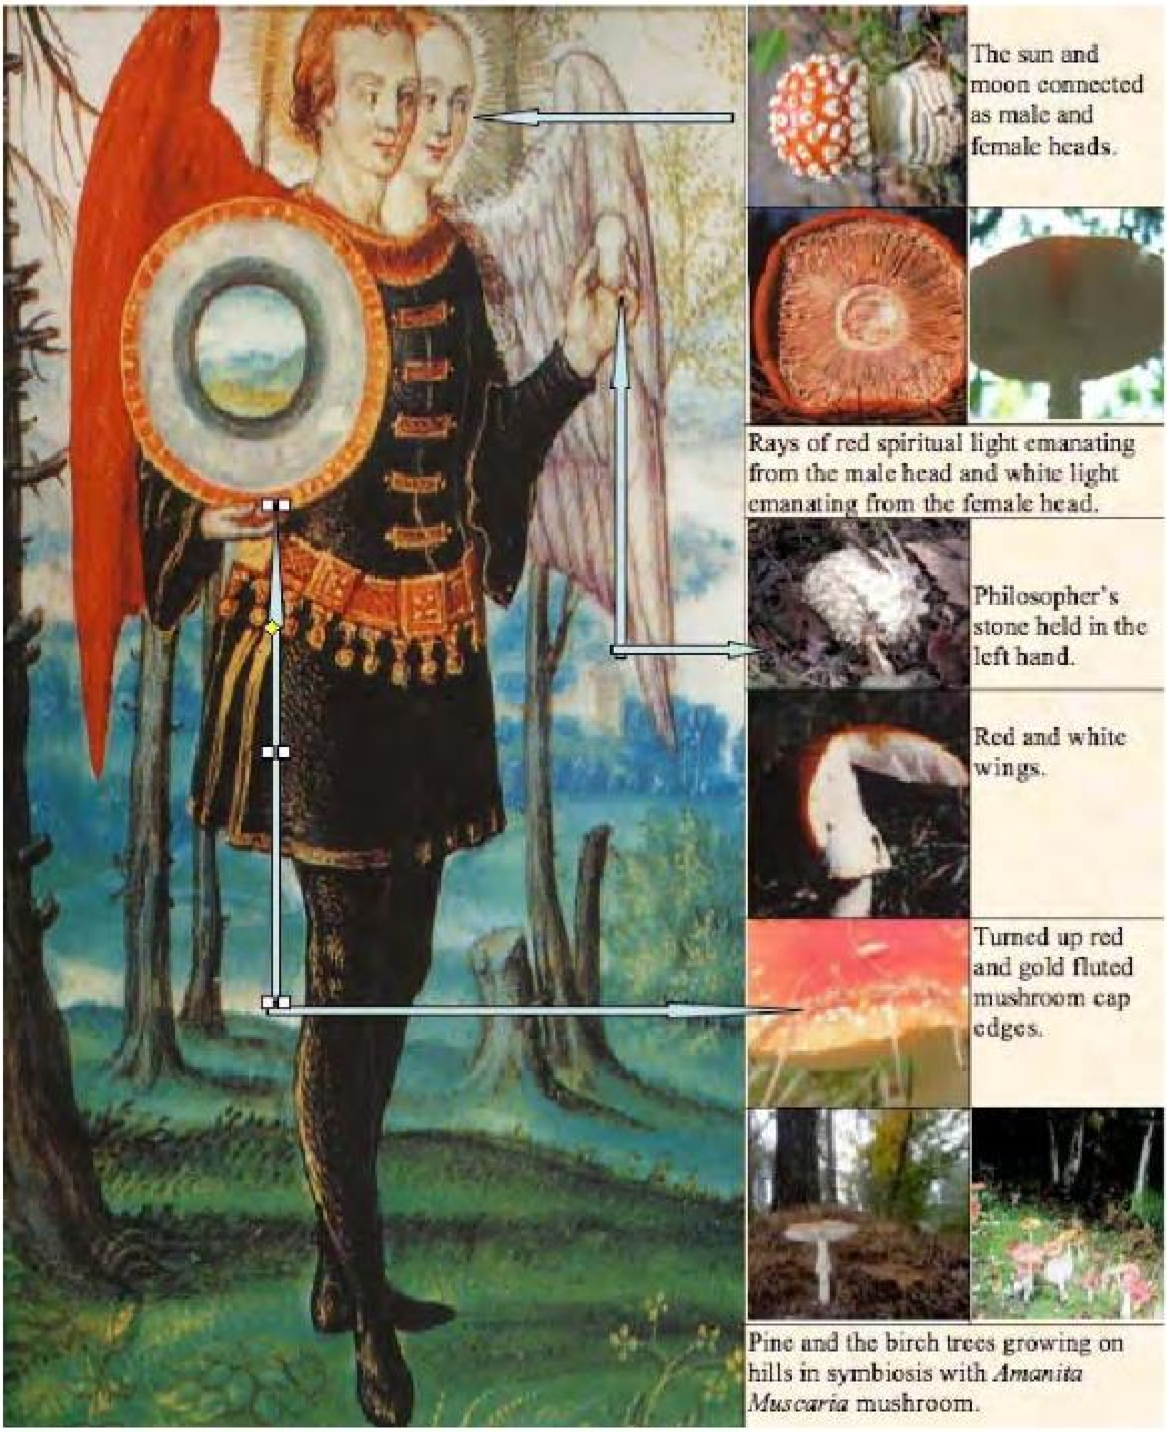
It also appears that Joseph may have been inebriated while composing the Book of Mormon. Martin Harris told A.C. Russell in 1834 that Joseph Smith was frequently intoxicated while translating.[70] It is possible that Joseph was not intoxicated as much with wine as with *Amanita muscaria* mushroom.

In addition to replicating aspects of Joseph Smith's visions and providing an allegorical story of gold plates upon which was written reformed Egyptian, a visionary mushroom is able to provoke Joseph Smith-like millennial zeal. In a 1962 experiment, visionary mushrooms were served to fifteen volunteers. As the entheogen began to take effect, one volunteer declared that he had been chosen by God "to announce to the world the dawning of the Messianic Age, a millennium of universal peace".[71]

Moreover, *Amanita muscaria* is known to increase physical strength, aggressiveness and confidence to the point of grandiose behavior all defining characteristics of Joseph Smith's personality.

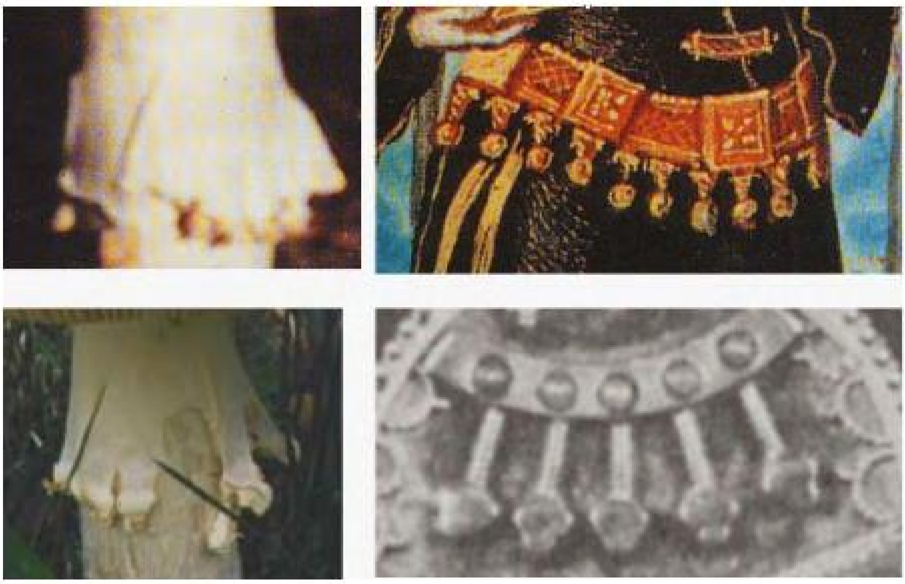
There may also be a connection between the *Amanita muscaria* mushroom, alchemical pictographic riddles and an amulet gifted by Joseph Smith to his most mystical plural wife, Eliza R. Snow.[72] While the rational for suggesting a connection between the *Amanita muscaria* mushroom and Joseph Smith's amulet is rather complex, it may be worth introducing the subject, which can be investigated further on www.mormonelixirs.org if one is interested.

Lance Owens has demonstrated a connection between Joseph Smith and hermetic traditions including alchemy.[73] Alchemists were absorbed in pursuing *prima materia*, a single substance that occasioned a direct and personal experience of illumination.[74] Clark Heinrich has shown that the most likely candidate for the alchemical entheogen is the *Amanita muscaria* mushroom.[75] To avoid persecution, Heinrich explains that alchemists kept the identity of *Amanita muscaria* mushroom secret by creating pictographic riddles.

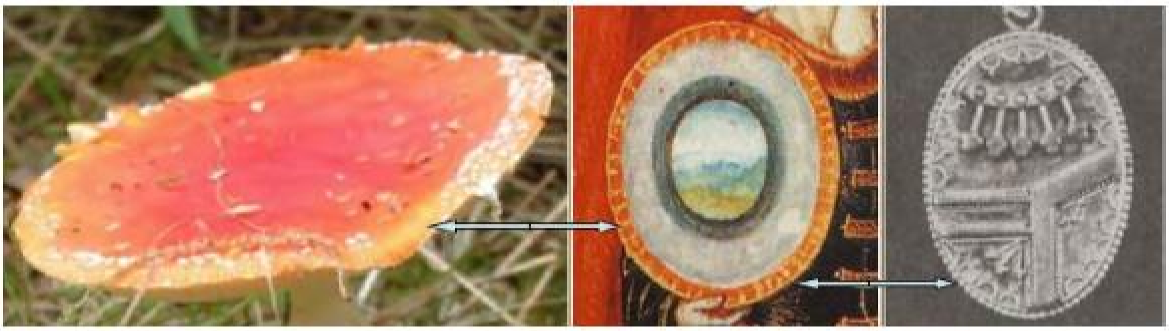


The sun and moon connected as male and female heads.
Rays of red spiritual light emanating from the male head and white light emanating from the female head.
Philosopher's stone held in the left hand.
Red and white wings.
Turned up red and gold fluted mushroom cap edges.
Pine and the birch trees growing on hills in symbiosis with *Amanita Muscaria* mushroom.

This 16th century alchemical pictographic[76] appears to be a personification of the *Amanita muscaria* mushroom.[77] Shown in the photos on the right are various stages of *Amanita muscaria* mushroom growth represented by the elements of the alchemical pictograph. Notice the figure's male and female heads representing the sun and moon phase of *Amanita muscaria* growth; the rays of red spiritual light emanating from the male head and the white spiritual light emanating from the female head represent the changing colors of the underside of the sacred mushroom cap; the philosopher's stone held in the left hand representing the brilliant white stage of early *Amanita muscaria* growth; the red and white wings representing the halved mushroom cap; the red and gold edged disk held in the figures right hand representing the red and gold fluted edges of a maturing upturned mushroom cap and finally the figure standing on a hill with pines to the left and the birches to the right representing the symbiotic relationship between those trees and the *Amanita muscaria* mushroom.



Another remarkable feature of the *Amanita muscaria* mushroom is the veil remnant found on the stem just underneath the cap. The veil's lower fringe appears to be trimmed with red-gold spheres dangling by ropes. This feature of the *Amanita muscaria* mushroom appears to be represented on the figures belt adorned with red-gold orbs. Further, there is a striking similarity between the personification of the *Amanita muscaria* veil on the figure's belt and the amulet belonging to Joseph Smith.

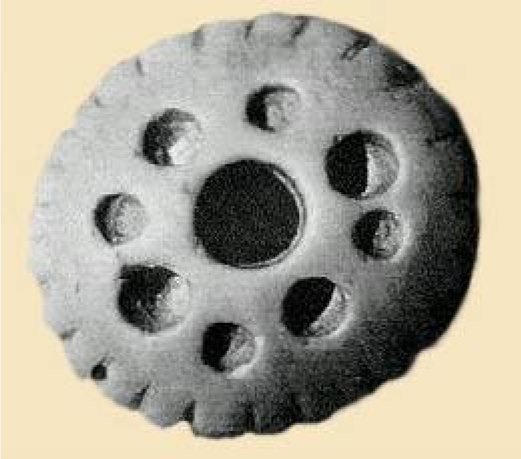


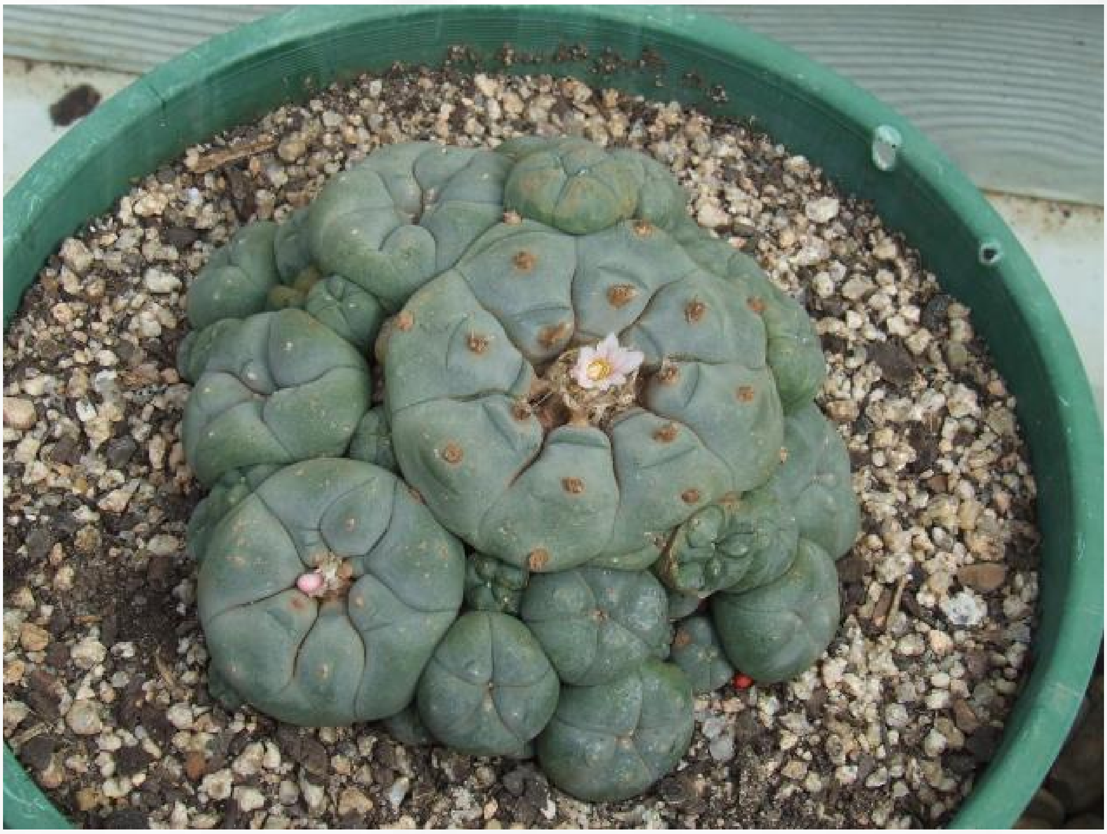
Another feature of the *Amanita muscaria* mushroom is the red and gold fluted edge of the mushrooms upturned cap. This appears to be represented in the red and gold fluted edge of the pictographic disk and on the outer edge of the Joseph Smith amulet. Other symbols on Joseph's amulet such as the compass and square, the down pointing arrows, the five orbs, and the half circles can be found on similar alchemical pictographs representing the *Amanita muscaria* mushroom.

In summary, the visionary *Amanita muscaria* mushroom appears as a meaningful thread in the Smith's dreams, in Joseph Smith Junior's first vision, in the account of Joseph finding the *Book of Mormon*, in the *Book of Mormon*'s translation, in the joint vision with Sidney Ridgon, in Joseph's strong and extravagant personality and in an alchemical amulet gifted to Eliza R. Snow.

Peyote

Another entheogen that can occasion experience which duplicates a portion of the *Book of Mormon* narrative, is the Peyote Cactus. At the time of his death, Joseph Smith possessed a seer stone shaped in the likeness of a visionary peyote button.





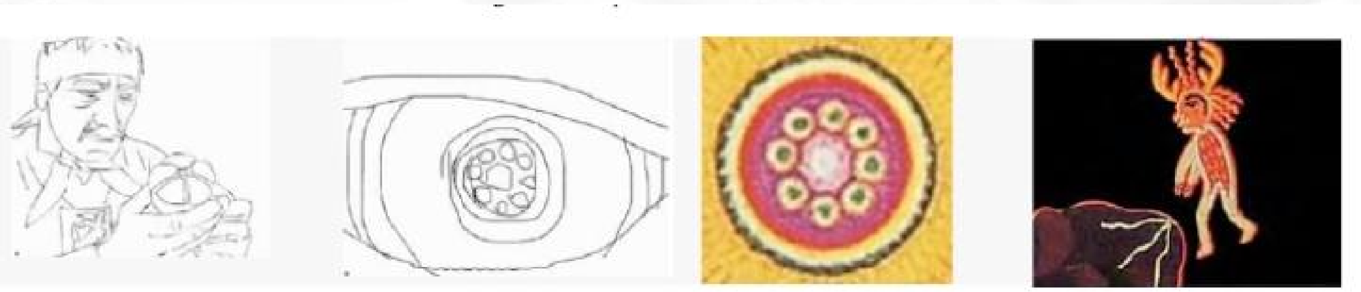
D. Michael Quinn writes that Joseph Smith found this stone, possibly in its rough unshaped form, along the Mississippi River's shore between 1839 and 1844. After Joseph's death, the stone was kept by Emma Smith and inherited by her second husband, Lewis Bidamon. It eventually made its way to the Wilford Wood Museum in Woods Cross, Utah. Quinn describes the stone as the size of a U.S. quarter dollar and "is the most intricate of those attributed to Smith. It has a hole through the center surrounded by eight smaller indentations, with tooled ridges around the edge".[78]

Gary R. Varner writes in *Menhirs, Domen and Circles of Stone: The Folklore and Magic of Sacred Stones* [Published 2004, Algora Publishing] in his introduction and on pages 14 and 15 that

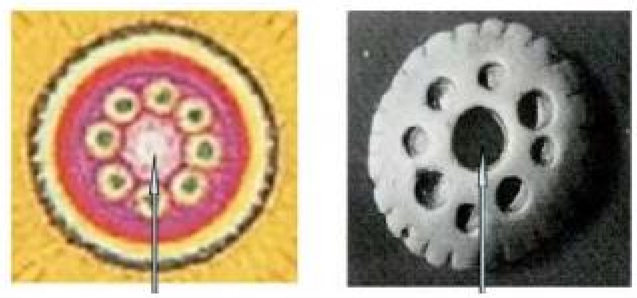
> Humans since the dawn of civilization have used stone to represent the holy, both by fashioning sacred symbols for themselves and by granting recognition to certain sites occurring naturally...

> Ethnographic evidence indicates that Comanche shamans used stones at least into the 1970's, if not later, in healing rituals. Ethologist David E. Jones wrote that a medicine woman he had studies "applied the stone peyote drum 'bosses' to the patient's face so that, through her powers, the positive qualities of these stones - firmness and stability - could be injected into the patient's contorted face to heal him." [Jones, David E. *Sanapia: Comanche Medicine Woman*. New York: Holt, Rinehart and Winston Case Studies in Cultural Anthropology, 1972, 96]
>
> Small stones with naturally occurring holes in them have been especially prized for their purported magical properties and in many cases, they were believed to be linked directly to the Goddess. In North Carolina, at least through the 1920s ... and Northumberland up to the early 20th century ... [and] in the Ozarks.

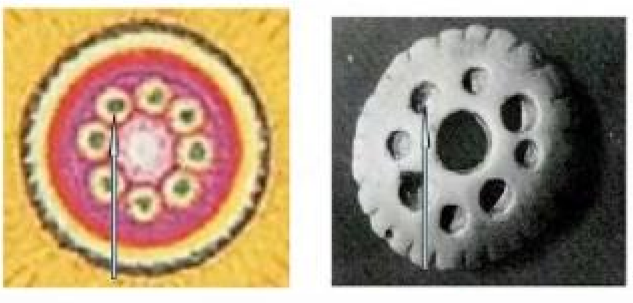
The peyote cactus resembles a pie cut in wedges, tufts of hair growing from each wedge and a central pinkish flower. To turn the Peyote cactus into a visionary sacrament, the hair tuffs of each pie shaped section are removed, the central flower is cored out and the tough bark is peeled off.[79]



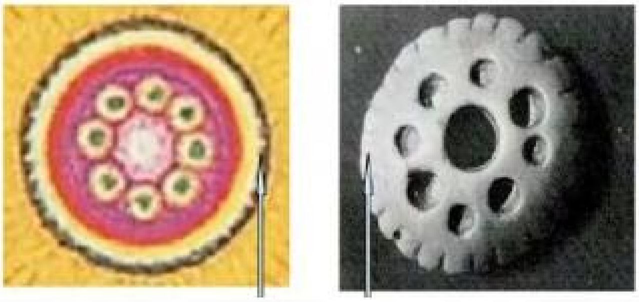
Shown above is a series of stills from a video[80] produced by a modern well educated Huichol Indian. The scenes depict a Shaman ingesting a prepared Peyote button and entering a visionary world. The first two images are of the shaman ritually contemplating the sacramental meal. Note the reflection of the peyote in the shaman's eye. This image has round edges, depressions where the tufts of hair were removed and a hole where the central flower was cored out. The next image is a depiction of the visionary transformation of the ingested peyote cactus demonstrated by its vivid colors and its scalloped edges radiating spiritual light, illuminating the spiritual world. The next photo shows a spirit or God seen in vision or perhaps the shaman in out-of-body flight.



Above is shown a comparison between the Huichol Indian representation of the visionary peyote cactus button and Joseph Smith's most intricate seer stone. There is a central hole allowing light to shine through in both the peyote cactus and the seer stone.



Surrounding the central hole on both the cactus and stone are eight circular depressions with shadows.



And finally, the edges of the visionary cactus and stone are both scalloped suggesting its entheogenic property of illuminating the spiritual world.

Why would Joseph Smith have a visionary peyote stone? What could peyote have to do with Joseph's visionary experience? The answer may be that peyote put Joseph Smith in contact with ancient Amerindian cultures gifting him with the material that was later incorporated into the *Book of Mormon*. The experience occasioned by mescaline, the psychoactive component of peyote, in a modern user replicates an account of Joseph Smith's boyhood visionary knowledge of the ancient Amerindian. Joseph's mother, Lucy Mack noted that even before receiving the gold plates, her son was gifted with an extensive knowledge of the inhabitants of ancient America.

> During our evening conversations, Joseph would … describe the ancient inhabitants of this continent, their dress, mode of traveling, and the animals upon which they rode; their cities, their buildings with every particular; their mode of warfare; and also their religious worship. This he would do with as much ease, seemingly, as if he had spent his whole life with them.[81]

A cactus like Peyote that contains mescaline could have occasioned direct experience with ancient Amerindian cultures.

Earl Crockett, a successful businessman and amateur ethnobotonist, gave an account that replicates Joseph Smith's recitals of ancient Amerindian culture. In a 2005 report, Crockett indicated that sometime earlier he had taken mescaline while sitting near a cave used by a mysterious Baja California Indian tribe that vanished long ago. After ingesting the cactus, Crockett explains

> I'm sitting there for however, who knows long, eyes open and I look up above the canyon wall and there's Venus. And this light came down from Venus and I went back up it and was gone. I learned who they were, how they dressed, how they got there, on and on and on and on and on.[82]

Interestingly, Joseph Smith's grandson, Frederick M. Smith, president of the Reorganized Church of Jesus Christ of Latter-day Saints participated in Amerindian peyote ceremonies. Shelby M. Barnes reports that President Smith experimented with peyote as early as 1913 and notes that President Smith

> … widely used [peyote] … [opening his mind] to the mysteries of human ecstasy as an essential element of religion … He was convinced that every human being had the potential to expand the limits of his or her mind.[83]

Like his great grandfather, Joseph Smith Junior, President Frederick M. Smith felt that even the least Saint should have access to the heavenly realms. In 1919, President Smith encouraged others in the RLDS Church to use peyote in a controlled manner[84] and defended peyote ceremonies from Federal intrusion.

Weaknesses of the Entheogenic Theory of Mormon Origins

It is theorized that psychedelics substances disinhibit unconscious material from reaching conscious awareness. Jung suggested that unconscious material, especially material in the collective unconscious is represented by myth and symbols. It is possible that Joseph Smith's genetic heritage combined with severel psychological and physical trauma when seven years old made material in Joseph Smith's unconscious easily "bleed" into the conscious during periods of meditation or stress. In this case, there is a low threshold for the release of endogenous psychedelics such as DMT (Dimethyltryptamine) that may have facilitated visionary experiences. In this case, exogenous psychedelics would not have been necessary. Additionally, it is possible that Joseph Smith selected men such as himself who had low thresholds for release of DMT. This seeker psyche was expunged from the church because of their destabilizing influence as suggested by Richard Bushman. In this case, the Kirkland excesses highly suggestive of exogenous psychedelics were unauthorized by Joseph Smith and the visions associated with the Kirtland temple were the result of the seeker psyche rather than psychedelics.

Even if the entheogenic theory of Mormon origins is incorrect, there is little doubt that psychedelics can facilitate visionary experiences remarkably similar if not indistinguishable from those experienced by Joseph Smith and early Mormon converts. If the final pathway for this visions is a psychedelic substance, whether externally administered or internally released, should seekers without a genetic disposition, be discouraged from taking psychedelics in a set and setting that is both suitable and safe? The primary transcendent experience, for some, is undoubtedly a boon, relieving depression and existential anxieties.

Implications

As Richard Bushman noted, it was Joseph Smith himself that connected early Mormon converts to heavenly visions and spiritual raptures by a power that he, himself possessed.[85] It is to the mystery of Joseph Smith's spiritual power that this presentation has addressed itself. This presentation has theorized that the main origin and ongoing wellspring of Joseph's spiritual power was his skilled utilization of the visionary *Datura* plant, the sacred *Amanita muscaria* mushroom and the revered peyote cactus. These natural chemical disinhibited the unconscious mind and by excluding light, revelations of mythic quality were generated. In the administration of these entheogens, it is hypothesized that Joseph Smith (using ritual i.e. set, setting, substance, support) was able to gift his followers with access to God and spiritual dimensions without the years of fasting, isolation, and self-torture employed by other mystic and spiritual leaders.

If the entheogen theory of the rise of Mormonism proves to be correct, it is probable that if Joseph Smith had lived to complete the Nauvoo temple, the visionary experiences surrounding its dedication would have eclipsed those of the Kirtland Pentecost in both glory and power. Further, there is reason to conjecture that if Joseph Smith had lived to be 85 as he speculated he might,[86] members would not have been asking in 1864 "why it is that we do not see more angels, have more visions, that we do not see greater and more manifestations of power [as did the first converts and leadership]?"

The fact that members of the LDS Church must look backward to the early years of the "restoration" suggests that Mormon Church had lost its mystical core early in its history. David Steindl-Rast addressed the question of the mystic in organized religion when he writes:

Mysticism has been democratized in our day. Not so long ago, "real" mystics were those who had visions, levitations, and bilocations and, most important, were those who had lived in the past; any contemporary mystic was surely a fake (if not a witch). Today, we realize that extraordinary mystical phenomena have little to do with the essence of mysticism. (Of course, genuine mystics had told us this all along; we just wouldn't listen.) We've come to understand mysticism as the experience of communion with Ultimate Reality (i.e., with "God," if you feel comfortable with this time-honored, but also time-distorted term).

Many of us experience a sense of communion with Ultimate Reality once in a while. In our best, most alive moments, we feel somehow one with that fundamental whatever-it-is that keeps us all going. Even psychological research suggests that the experience of communion with Ultimate Reality is nearly universal among humans. So we find ourselves officially recognized as bona fide mystics. Some of us even sense the challenge to translate the bliss of universal communion into the nitty-gritty of human community in daily living. That's certainly a step forward.

Like every step forward in life, however, the discovery of mysticism as everyone's inalienable right brings with it a puzzling tension. Those who feel this tension most keenly are people who have long been members of an established religion, with its doctrines, ethical precepts, and rites. They may discover the mystical reality inside the religious establishment or outside of it: either in church or on a mountaintop, while listening to

Bach's BMinor Mass, or while watching a sunset. In any case, but especially out in nature, those who taste mystical ecstasy may begin to sense a discrepancy between this undeniably religious experience and the forms that normally pass as religious. If the religious pursuit is essentially the human quest for meaning, then these most meaningful moments of human existence must certainly be called "religious." They are, in fact, quickly recognized as the very heart of religion, especially by people who have the good fortune of feeling at home in a religious tradition. And yet, the body of religion doesn't always accept its heart. This can happen in any religious tradition, Eastern or Western. To the establishment, after all, mysticism is suspect. The established religion asks: Why is there a need for absorption in the Cloud of Unknowing when we have spelled out everything so clearly? And isn't that emphasis on personal experience a bit egocentric? Who can be sure that people standing on their own feet won't go their own way? These suspicions gave rise to the famous saying that "myst-i-cism begins with mist, puts the I in the center, and ends in schism." ...

The question we need to tackle is this: How does one get from mystic experience to an established religion? My one-word answer is: inevitably. What makes the process inevitable is that we do with our mystical experience what we do with every experience, that is, we try to understand it; we opt for or against it; we express our feelings with regard to it. Do this with your mystical experience and you have all the makings of a religion. This can be shown.[87]

If the entheogen theory of the rise of Mormonism proves to be correct, it is probable that if Joseph Smith had lived to complete the Nauvoo temple, the visionary experiences surrounding its dedication would have eclipsed those of the Kirtland Pentecost in both glory and power. Further, there is reason to conjecture that if Joseph Smith had lived to be 85 as he speculated he might,[86] members would not have been asking in 1864 "why it is that we do not see more angels, have more visions, that we do not see greater and more manifestations of power [as did the first converts and leadership]?"

Appendices

James Arthur & Alex Andoven. *The Golden Mushroom Plates of Mormonism: Did Joseph Smith, the Founder of the Latter Day Saints (Mormon) Religion, Consume Psychedelic Fungi?* Unpublished. A selection from the unfinished chapter titled "The Host". Found at http://groups.yahoo.com/group/egodeath/message/4011

Many organisms are parasitic but others, which are associated with a host life form, are not. They are Symbiotic life forms, living in harmony with another life form and thriving off of its energy and substance while also feeding the other with its own energy and substance. Mushrooms do this very thing, and the *Amanita* is one of the most famous for it. The mushroom grows in a relationship with coniferous trees (Pine, Spruce, Cedar etc.) because the mushroom is only the fruit of a bigger organism, which actually lives underground. This is the mushroom's main body, mycelium, an organism that is symbiotic with the tree because it is attached to the tree's root system and thrives off of the energy and substance of the tree, from its roots. The mycelium is the host for the tree and the tree is the host for the mycelium, and thus the mushroom, and these hosts live in a Mycorhizzal Symbiotic relationships with each other. So the mushroom is a host in the botanical, ethnobotanical, esoteric, magickal, occultic, alchemical senses of the word. The mushroom can also be seen, by a visionary imbiber, as a host for a state of mind, the host to a party in an extra dimensional realm, the host for a visit to another state of consciousness. The lord of hosts in this regard can also be interpreted to mean; of all the hosts that the planet has to offer, in this sense, Peyote, *Psilocybe* (another species of entheogenic mushrooms), Marijuana, Opium Poppies, Coca leaves etc. The Lord of all hosts is the *Amanita muscaria*. Certainly it has more religious connections than any other specific entheogen. Its appearance, striking color and majesty (Kings crowns, robes, and scepters are designed after its likeness) make it a brilliant and obvious living presence on our planet. The Lord of Hosts is a perfect euphemism for the mushroom and its esoteric interpretation, in this sense, expounds on the understanding of the meaning of the religion, as a good, deeper, secret revelation should. Of course, as would be expected, another meaning for the term host is the sacramental water, or consecrated bread, which is of course the body of jesus, the mushroom, the hidden manna, the host which lives under the Pine tree ('Christmas tree') it's host. It bears mentioning here again that the mushroom is also a symbiotic with the Birch tree, the trees which were in the Sacred Grove.

Delusions of Grandeur

It is no secret that Joseph Smith believed himself to be a messianic figure, the one man capable of ushering in the millinial reign of Jesus Christ. Where could this distortion of reality originated? One possiblility is the use of psychedelics.

One of the major negative side effect of psychedelic experimentation is delusional ideation, and one of the most common pathologies associated with frequent high-dose psychedelic experimentation is persistent recurring delusions of grandeur. Delusional ideation within the psychedelic state is to be expected; but when delusional ideations cross the boundary from dream-state into waking state, this is where the trouble begins...

The first thing to keep in mind is that persistent recurring delusions of grandeur (PRDoG) don't typically take hold after a single isolated psychedelic voyage. Though one might run up against some savory delusional, messianic, or paranoid ideation in a single trip, the content derived from a single psychedelic session is often easily forgotten, dismissed, or toyed with for a while before it simply fades away. The key patterns we are looking for when approaching persistent delusions of grandeur are 1) high dose ranges, 2) high frequency of use, 3) ingestion contexts which isolate the user from external stimulus, and 4) ingestion contexts that revolve around repetitive rituals, themes, or patterns. (James Kent, Psychedelic Information Theory: Chapter 20: Messianic Ideation & Delusions of Grandeur. http://www.tripzine.com/listing.php?id=pit_toc)

Abstract

In recent years, the scientific study of meditation and psychedelic drugs has seen remarkable developments. The increased focus on meditation in cognitive neuroscience has led to a cross-cultural classification of standard meditation styles validated by functional and structural neuroanatomical data. Meanwhile, the renaissance of psychedelic research has shed light on the neurophysiology of altered states of consciousness induced by classical psychedelics, such as psilocybin and LSD, whose effects are mainly mediated by agonism of serotonin receptors. Few attempts have been made at bridging these two domains of inquiry, despite intriguing evidence of overlap between the phenomenology and neurophysiology of meditation practice and psychedelic states. In particular, many contemplative traditions explicitly aim at dissolving the sense of self by eliciting altered states of consciousness through meditation, while classical psychedelics are known to produce significant disruptions of self-consciousness, a phenomenon known as drug-induced ego dissolution. In this article, we discuss available evidence regarding convergences and differences between phenomenological and neurophysiological data on meditation practice and psychedelic drug-induced states, with a particular emphasis on alterations of self-experience. While both meditation and psychedelics may disrupt self-consciousness and underlying neural processes, we emphasize that neither meditation nor psychedelic states can be conceived as simple, uniform categories. Moreover, we suggest that there are important phenomenological differences even between conscious states described as experiences of self-loss. As a result, we propose that self-consciousness may be best construed as a multidimensional construct, and that "self-loss," far from being an unequivocal phenomenon, can take several forms. Indeed, various aspects of self-consciousness, including narrative aspects linked to autobiographical memory, self-related thoughts and mental time travel, and embodied aspects rooted in multisensory processes, may be differently affected by psychedelics and meditation practices. Finally, we consider long-term outcomes of experiences of self-loss induced by meditation and psychedelics on individual traits and prosocial behavior. We call for caution regarding the problematic conflation of temporary states of self-loss with "selflessness" as a behavioral or social trait, although there is preliminary evidence that correlations between short-term experiences of self-loss and long-term trait alterations may exist.

Keywords: psychedelics, meditation, self-consciousness, consciousness, bodily self-consciousness, autobiographical memory, mind wandering, mental time travel.

Introduction

The scientific study of meditation and psychedelic drugs has seen remarkable developments in recent years. The increased focus on meditation in cognitive neuroscience has led to a cross-cultural classification of standard meditation styles validated by functional and structural neuroanatomical data (Lutz *et al.*, 2008; Dahl *et al.*, 2015; Fox *et al.*, 2016). Meanwhile, the renaissance of psychedelic research (Carhart-Harris and Goodwin, 2017) has shed light on the neurophysiology of altered states of consciousness induced by classical hallucinogens, such as psilocybin and LSD, whose effects are mainly mediated by agonism of serotonin receptors, and the serotonin 2A receptor subtype specifically (Carhart-Harris *et al.*, 2012, 2016b; Nichols, 2016). However, few attempts have been made at bridging these two domains of inquiry, despite increasing evidence of overlap between the phenomenology and neurophysiology of meditation practices and psychedelic states.

In particular, many contemplative traditions explicitly aim at dissolving the sense of self by eliciting altered states of consciousness through meditation (Austin, 2000; Josipovic, 2010; Vago and Silbersweig, 2012; Dahl *et al.*, 2015), while classical psychedelics are known to produce significant disruptions of self-consciousness[1], a phenomenon known as "drug-induced ego dissolution" (Millière, 2017; Nour and Carhart-Harris, 2017; DIED). In this article, we discuss available evidence regarding convergences and differences between phenomenological and neurophysiological data on meditation practice and psychedelic drug-induced states, with a particular emphasis on alterations of self-experience. While both meditation and psychedelics are suspected to disrupt self-consciousness and its underlying neural processes, this general hypothesis requires careful qualification.

[1] By "self-consciousness," we refer in this article to a subject's consciousness of themselves - also called "sense of self," "self-awareness," "phenomenal selfhood," or "self-experience." Importantly, "self-consciousness" does not refer here to the social awareness of being the object of the observation of others.

First, it is important to emphasize right away that neither meditation nor psychedelic states can be conceived as simple, uniform categories. Many variables modulate the subjective effects of contemplative practice and psychedelics, including the style of meditation or the drug and dosage used, as well as personal factors such as level of experience and personality traits. In particular, dramatic disruptions of self-consciousness seem to occur mostly for highly experienced meditators or with high doses of psychedelics. Thus, we suggest that both meditation and psychedelics can induce a wide variety of global states of consciousness, but these states are sensitive to a multitude of factors in addition to the specific inducers we are highlighting here[2].

[2] From a methodological perspective, disruptions of self-consciousness induced by meditation might be more challenging in terms of laboratory production, while disruptions of self-consciousness following the administration of psychedelic drugs might be more strictly dose-dependent and therefore easier to produce in a controlled setting. In a similar vein, the choice of baseline conditions and control groups is a multi-faceted issue in meditation research, often limiting interpretability, whereas placebo-controlled designs are the default for studies on psychedelics. Nonetheless, true placebo control is difficult to achieve with psychedelics, given their vivid and characteristic subjective effects.

In addition, we suggest that there are important phenomenological differences even between conscious states described as experiences of self-loss. As a result, we propose that self-consciousness may be best construed as a multidimensional construct, and that "self-loss" or "ego dissolution," far from being an unequivocal phenomenon, can take several forms. Indeed, various aspects of self-consciousness, including narrative aspects linked to autobiographical memory, self-related thoughts and mental time travel, and embodied aspects rooted in multisensory processes, may be differently affected by psychedelics and meditation practices. It is also worth acknowledging that "self-loss" or "ego dissolution" may be a non-linear phenomenon that only occurs after a critical inflection point has been reached.

Finally, we consider long-term outcomes of experiences of self-loss induced by meditation and psychedelics on individual traits and prosocial behavior. We call for caution regarding the problematic conflation of temporary states of self-loss with "selflessness" as a personal or social trait, although it remains possible that correlations exist between short-term experiences and long-term dispositions in this regard.

The nuroscience of meditation and psychedelics: an overview

Meditation refers to a set of cognitive training techniques and practices that aim to monitor and regulate attention, perception, emotion and homeostasis (e.g., breathing rate) (Fox and Cahn, forthcoming; Tang *et al.*, 2015). Such techniques and practices have been developed in many different cultures and spiritual traditions, yielding more than a 100 varieties of meditation. Most scientific research on the topic has focused on techniques originating in the Buddhist tradition from China, Tibet, India and Southeast Asia, with a particular focus on practices often subsumed under the loose category of mindfulness meditation (see **Box 1**; on the limitations of the notion of mindfulness, see Dam *et al.*, 2018). Nonetheless, there are a growing number of studies on meditative practices from other contemplative traditions - including yogic, Hindu, Christian, Sufi, shamanic and transcendental practices.

To address this remarkable diversity of traditions, researchers have also sought to categorize the main styles of meditation across cultural, geographical and historical contexts, based on the core goals and principles of the mental techniques involved (Lutz *et al.*, 2008; Travis and Shear, 2010; Nash and Newberg, 2013). Common styles of meditation include focused attention meditation (FA) - which requires sustaining one's attention on a particular object or sensation such as the breath - , open monitoring meditation (OM) - which involves a non-judgmental, non-selective awareness of the present moment - , loving-kindness and compassion meditation (LK) - which involves the cultivation of compassion toward oneself and others - , and mantra recitation (MR) - which involves the repetition of a sound, word or sentence (see Box 1). The subjective effects of meditation are multifaceted, including enhanced attention and sensory processing (Brown, 1977; Jha *et al.*, 2007), largely positive emotions and mood (Ortner *et al.*, 2007; Davidson and Lutz, 2008; Lutz *et al.*, 2008), increased cognitive flexibility and creativity (Horan, 2009; Capurso *et al*., 2014; Ding *et al*., 2014; Berkovich-Ohana *et al*., 2017), and, in some cases (usually with increasing expertise) dramatic disruptions of one's sense of self (Austin, 2006; Dorjee, 2016; Berkovich-Ohana and Wittmann, 2017).

BOX 1 | Glossary.

Drug-induced Ego Dissolution (DIED). A family of acute effects produced by high doses of psychedelic drugs, typically reported as a loss of one's sense of self and self-world boundary.
Focused Attention (FA). A common style of meditation that involves sustaining one's attentional focus on a particular object, either internal (e.g., breathing) or external (e.g., a candle flame). The practitioner is instructed to monitor their attention, notice episodes of distraction (mind-wandering), and bring their attention back to the object. FA is usually the starting point for novice meditators.
Loving-Kindness Meditation (LK). A common style of meditation that focuses on developing compassion and love for oneself and others, gradually extending the focus of empathy to foreign and disliked individuals or even all living-beings. While loving-kindness meditation incorporates technical elements from FA and open monitoring (OM, defined below), it has a distinct phenomenology and neural correlates due to its emotional content.
Mantra Recitation (MR). A style of meditation that involves repeating a sound, word or sentence, either aloud or in one's mind, in order to calm the mind and avoid mind-wandering. Although MR is arguably a form of Focused Attention meditation, it is distinguished by its speech component and may have distinct neural correlates.
Meta-Awareness. The ability to take note of the content of one's current mental state. In the context of meditative practices, meta-awareness often refers specifically to the meditator's awareness of episodes of mind-wandering (spontaneous thoughts arising during meditation).
Mindfulness Meditation. A group of practices aimed at cultivating mindfulness, typically defined as a state of non-judgmental awareness to one's present moment experience. Mindfulness meditation may refer to both focused attention (FA) and open monitoring (OM) practices.
Non-Dual Awareness (NDA). In many contemplative traditions (including Advaita Vedanta and Kashmiri Shaivism within Hinduism, and Dzogchen and Mahāmudrā within Buddhism), the practice of meditation aims at recognizing the illusory nature of the subject-object dichotomy that allegedly structures ordinary conscious experience, thus revealing the "non-dual awareness" that lies at the background of consciousness.
Open Monitoring (OM). A common style of meditation that aims at bringing attention to the present moment and openly observing mental contents without getting caught up in focusing on any of them. Open monitoring meditation traditionally follows focused awareness, as the practitioner learns to switch from a narrow attentional focus on an object to a global awareness of the present moment.
Psychedelic Drugs. A family of psychoactive compounds whose complex effects on the quality of conscious experience are mainly mediated by their action on serotonin receptors in the brain (and specifically their binding to and stimulation of serotonin 2A receptor subtype). Psychedelic substances include mescaline, psilocybin (so-called "magic mushrooms"), Lysergic Acid Diethylamide (LSD), *N,N*-Dimethyltryptamine (DMT), and the DMT-containing brew Ayahuasca.
Pure Consciousness (PC). A state of consciousness described as "objectless" or entirely devoid of phenomenal content. While the possibility of such states is very controversial, certain conscious states induced by some meditative practices and classical psychedelics might lack at least ordinary phenomenal content. In the Hindu and Buddhist traditions, the practice of Samadhi is often described as leading to the experience of PC.

Classic psychedelics, also known as classic hallucinogens, are a family of psychoactive substances that exert their subjective effects primarily by agonism (or partial agonism) of serotonin 2A (5-HT_{2A}) receptors (Halberstadt, 2015; Nichols, 2016). Psychedelics include molecules found in the natural world such as psilocybin (a prodrug of psilocin found in so-called "magic mushrooms"), mescaline (found in various South

American cacti, including Peyote, San Pedro and Peruvian torch), *N,N*-Dimethyltryptamine (DMT, found in many plants such as *Mimosa tenuiflora*, *Diplopterys cabrerana*, and *Psychotria viridis*, and used in combination with monoamine oxidase inhibitors in the shamanic brew Ayahuasca) and 5-MeO-DMT (found in the toxin of the toad *Bufo alvarius*, as well as a wide variety of plants such as *Anadenanthera peregrina* used in yopo snuff). Psychedelics also include many synthetic compounds, such as lysergic acid diethylamide (LSD) and phenethylamines of the 2C-*x* family (e.g., 2C-B). The subjective effects of psychedelics are complex and multifaceted, including visual and auditory distortions and complex closed-eye "visions," profound changes in emotions and mood, heightened sensitivity to internal and external context, and at higher doses, dramatic alterations of self-consciousness known as drug-induced ego dissolution (DIED) (Strassman *et al.*, 1994; Vollenweider *et al.*, 1998; Studerus *et al.*, 2011; Carhart-Harris *et al.*, 2012, 2016b; Schmid *et al.*, 2015; Fox *et al.*, 2016; Millière, 2017).

Neural Correlates of Meditative Practices

Over the past 20 years, a large number of neuroimaging studies have investigated various styles of meditation, using electroencephalography (EEG), functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) to measure changes in blood flow and electrical activity in the brain during meditation. This research program seeking to isolate the neural correlates of various meditation practices has come to be known as contemplative neuroscience. Interestingly, the wealth of data collected from these studies has begun to reveal that meditation practices from distinct traditions relying on similar mental techniques, also share some common neural correlates. A recent meta-analysis of 78 functional neuroimaging studies of meditation found dissociable patterns of activation and deactivation for four common styles of meditation: focused attention (FA), mantra recitation (MR), open monitoring (OM), and loving-kindness meditation (LK) (Fox *et al.*, 2016; see **Table 1**).

Table 1 - Significant clusters of activation/deactivation in four common meditation styles from a meta-analysis of 78 neuroimaging studies (Fox *et al.*, 2016).

	Focused Attention (FA)	Mantra Recitation (MR)	Open Monitoring (OM)	Loving-Kindness (LK)
Significant activation clusters	PMC Dorsal ACC	Broca's Area PMC SMC	Insula IFG SMA/preSMA PMC	IPL Anterior Insula
Significant deactivation clusters	PCC IPL	Anterior Insula	Thalamus	/

FA was correlated with significant activation clusters in executive brain areas such as the premotor cortex and the dorsal anterior cingulate cortex, which may underlie top-down regulation of attention and monitoring of spontaneous thoughts. FA was also correlated with the deactivation of two important hubs of the so-called default-mode network (DMN) namely, the posterior cingulate cortex and inferior parietal lobule, involved in a plethora of introspection-related functions including self-reflection, mind-wandering, autobiographical memory recollection, mental time travel to the future and imagination more broadly. The main clusters of activation for MR were found in the motor control network (Broca's area, premotor cortex and supplementary motor cortex) and the putamen. The involvement of these regions in speech production and attention regulation is consistent with the practice of mantra recitation, which relies on the constant repetition of a phrase either in one's mind or out loud. MR was also associated with a significant deactivation cluster in the anterior insula, suggesting that the focus on a repeated phrase is linked to decreased awareness of bodily sensation.

By contrast, OM was found to be correlated with activation clusters in the insular cortex, involved in awareness of interoceptive signals, as well as in brain regions associated with the voluntary control of thought and action, such as the left inferior frontal gyrus, the pre-supplementary and supplementary motor areas, and the premotor cortex. OM was also associated with the deactivation of the right thalamus, a region involved in filtering out sensory stimuli (sensory gating), suggesting that the increased focus of awareness during OM is mediated by decreased sensory gating. Finally, significant activation clusters for LK were found in the right somatosensory cortices, the inferior parietal lobule and the right anterior insula, while no significant deactivation cluster was found. Although these four meditation styles are clearly dissociated by their neural correlates, Fox and colleagues found a few recurrent patterns of activity modulation, in particular in the insular cortex, an important multisensory area heavily involved in interoceptive awareness (Craig, 2002; Simmons *et al.*, 2013).

It is worth noting that distinct styles of meditation were found to modulate the activity of the insula in different ways, namely activation for FA, OM, and LK, and deactivation for MR. Nonetheless, the involvement of the insula in all four styles of meditation points toward the central role of the attentional control of bodily awareness, and awareness of breathing in particular, during various contemplative practices. Other convergent patterns of activity were found to a lesser extent in regions involved in the regulation of attention such as the premotor cortex, supplementary motor area and dorsal cingulate cortex (Fox *et al.*, 2016).

Importantly, and albeit not emphasized by Fox *et al.* (2016), attenuation of either activity or functional connectivity in the default mode network (DMN), a large-scale intrinsic network which is highly active at rest but less active during goal-directed tasks (Raichle *et al.*, 2001), was shown for MR (Berkovich-Ohana *et al.*, 2015), and in many studies of mindfulness meditation (combining FA and OM in different degrees). These studies reported a decrease of activity in key nodes of the DMN, particularly in the medial prefrontal cortex (Farb *et al.*, 2007, 2013; Brewer *et al.*, 2011; Scheibner *et al.*, 2017) and in the posterior cingulate cortex (Brewer *et al.*, 2011; Ives-Deliperi *et al.*, 2011; Pagnoni, 2012; Brewer and Garrison, 2014; Lutz *et al.*, 2016; Scheibner *et al.*, 2017), compared to meditation-naïve controls or within-group resting state (reviewed by Tang *et al.*, 2015). While DMN deactivation is not specific to mindfulness meditation, it has been found to be more pronounced during meditation than during other cognitive tasks (Garrison *et al.*, 2015). Moreover, several studies reported altered connectivity during different types of meditation most consistently in association with the DMN (Tang *et al.*, 2015). Specifically, within-DMN connectivity was found to be reduced during LK (Garrison *et al.*, 2014).

Neural Correlates of Psychedelic States

Recent years have seen a renaissance of scientific research on psychedelic drugs, using modern neuroimaging techniques to gather insight into the neural correlates of their vivid subjective effects (see dos Santos *et al.*, 2016 for a review). Early neuroimaging studies using PET and single-photon emission computed tomography (SPECT) after administration of psilocybin and mescaline found excitatory effects on frontal cortical areas, medial temporal lobes and the amygdala (Hermle *et al.*, 1992; Vollenweider *et al.*, 1997, 1998; Gouzoulis-Mayfrank *et al.*, 1999). By contrast, recent fMRI of psilocybin and ayahuasca found significant reductions in activity across many brain areas, including frontal and temporal cortical regions, as well as hubs of the DMN (Carhart-Harris *et al.*, 2012; Palhano-Fontes *et al.*, 2015; see Table 2). This apparent discrepancy could be due to the much greater timescales used by PET/SPECT compared to fMRI (Carhart-Harris *et al.*, 2012).

Recent fMRI studies also revealed alterations of resting-state functional connectivity in key nodes of the DMN after administration of psilocybin (Carhart-Harris *et al.*, 2012, 2013; Tagliazucchi *et al.*, 2014; Lebedev *et al.*, 2015), ayahuasca (Palhano-Fontes *et al.*, 2015) and LSD (Carhart-Harris *et al.*, 2016b; Tagliazucchi *et al.*, 2016; see **Table 2**). Researchers found increased integration between cortical regions under ayahuasca (de Araujo *et al.*, 2012), psilocybin (Carhart-Harris *et al.*, 2013; Roseman *et al.*, 2014), and LSD (Carhart-Harris *et al.*, 2016b; Tagliazucchi *et al.*, 2016; Müller *et al.*, 2017). Finally, psilocybin and LSD were found to produce an enhanced repertoire of dynamical brain states (Tagliazucchi *et al.*, 2014; Atasoy *et al.*, 2017) and increased spontaneous MEG signal diversity (Schartner *et al.*, 2017).

Psychedelic drugs are known to produce short-term, dramatic effects on self-consciousness, especially at higher doses. This phenomenon is known as drug-induced ego dissolution (DIED); it is described a loss of one's sense of self and self-world boundaries, together with a concomitant oceanic feeling of "oneness" or "unity" (Letheby and Gerrans, 2017; Millière, 2017; Nour and Carhart-Harris, 2017). Such effects on self-consciousness had already been reported in early studies with mescaline (Mayer-Gross and Stein, 1926; Beringer, 1927; Guttmann and Maclay, 1937), LSD (Anderson and Rawnsley, 1954; Savage, 1955; Von Mering *et al.*, 1955; Bercel *et al.*, 1956; Klee, 1963; Sedman and Kenna, 1964; Pahnke and Richards, 1966) and psilocybin (Rümmele and Gnirss, 1961; Pahnke, 1966). Recent studies have sought to investigate the neural correlates of DIED, using correlations between questionnaire items and neuroimaging data. The main correlates of DIED, summarized in **Table 3**, include increased functional connectivity between the DMN and a task-positive network (Carhart-Harris *et al.*, 2013), decreased integrity of the DMN (i.e., decreased within network correlation of timecourses) (Carhart-Harris *et al.*, 2016b) and salience network (Lebedev *et al.*, 2015), decreased connectivity between the parahippocampal and retrosplenial cortices (Carhart-Harris *et al.*, 2016b), increased entropic brain activity (Lebedev *et al.*, 2016) and spontaneous MEG signal diversity (Schartner *et al.*, 2017), and decreased mean energy and fluctuations of low frequency connectome harmonics (Atasoy *et al.*, 2017).

Alterations of self-consciousness induced by meditation and psychedelics

While it is often claimed that meditation and psychedelic drugs are both able to induce "selfless" states of consciousness, that is conscious states entirely lacking a sense of self, this statement requires qualification. Indeed, "self-loss" and related expressions such as "ego dissolution" are notoriously ambiguous notions. Self-consciousness itself may be best construed as a multidimensional construct including somatosensory, agentive, narrative and social components (Gallagher, 2000, 2013; Zahavi, 2014; Seth and Friston, 2016). A conscious state in which one of these aspects is radically disrupted may be described as "selfless" in one respect, although a subject undergoing such a state could retain other forms of self-consciousness. Therefore, it is important to investigate which aspect(s) of self-consciousness can be disrupted by meditation and psychedelics, and whether both modes of induction may alter self-consciousness in similar ways. In addition, there is a further question regarding the possibility of truly "selfless" states, namely conscious mental states lacking *any* kind of self-consciousness. While some meditative practices and psychedelic drugs have been hypothesized to produce such "selfless" states, this claim needs to be supported by an examination of phenomenological reports in light of the distinction between different aspects of self-consciousness. In this section, we discuss the ways in which meditation and psychedelics may disrupt narrative, agentive and somatosensory aspects of self-consciousness, either in isolation or in combination. Moreover, we critically examine theoretical discussions and self-reports about states of "non-dual awareness" and "pure consciousness" allegedly induced by meditation.

Disruption of Narrative Aspects of Self-Consciousness

The familiar experience of thinking about oneself is perhaps the most salient form of self-consciousness. In philosophy of mind, this is also known as having *de se* thoughts, namely thoughts that involve the first-person concept and are naturally expressed using the first-person pronoun (García-Carpintero, 2015). *De se* thoughts themselves come in different flavors, which are more or less egocentric. Thus, one may explicitly reflect on one's personality traits or one's life trajectory, both of which are important elements of an individual's identity. This category of *de se* thought broadly pertains to the entertainment of core self-related beliefs, and is often linked to the notion of narrative selfhood - the stories we tell ourselves about the kind of person we are or want to be. Admittedly, this kind of *de se* thought only occurs sporadically in the waking state, because we are not constantly reflecting on our personal identity. However, *de se* thoughts also include more mundane and pervasive instances of mind-wandering, such as wondering what one will have for dinner. Such thoughts also link back to the self, insofar as they engage the first-person concept, even if they are not directly related to fundamental beliefs about one's identity. More generally, this family of self-referential cognitive content includes not only *de se* thoughts about the present moment, but also autobiographical memory retrieval and self-centered mental time travel to the future, both of which also crucially involve the self. Together, these self-referential mental episodes constitute what may be called narrative self-consciousness, namely the complex sequences of self-centered thoughts, memories and imaginings that weave the narrative of our daily lives and shape our core self-related beliefs (Damasio, 1999; Gallagher, 2000; Schechtman, 2011).

There are at least two ways in which narrative self-consciousness may be disrupted. First, the rate of occurrence of self-referential thought and mental time travel may be dramatically reduced, or altogether suppressed, during a certain time interval. There is convincing evidence from experience sampling studies that mind-wandering and mental time travel is more ubiquitous in the waking state than we might think, due to the fact that we are often unaware of such episodes (Smallwood and Schooler, 2006; Killingsworth and Gilbert, 2010; Baird *et al*., 2011). Moreover, daily mind-wandering episodes are predominantly future-focused, and frequently involve the planning and anticipation of personal goals, known as autobiographical planning (Baird *et al*., 2011; D'Argembeau, 2016). Thus, it is not exaggerated to say that a large part of our lives is spent entertaining self-involving thoughts, insofar as this includes spontaneous *de se* thoughts about the future. Most contemplative practices, especially in the Buddhist tradition, explicitly aim at increasing meta-awareness of mind-wandering, namely monitoring and taking explicit note of spontaneous thoughts, in order to disengage from them and re-focus attention back onto a particular object (such as the breath or a mantra) or on a wider awareness of the present moment (Hasenkamp, 2018). Once attention has been stabilized and the mind "quieted," meditators can undergo prolonged conscious episodes entirely lacking in self-referential thoughts[3].

This is consistent with the neurophysiological basis of mindfulness meditation reviewed in the previous section. While key nodes of the DMN such as the mPFC and the PCC are especially active during mind-wandering (Christoff *et al*., 2009; Fox *et al*., 2015), a number of studies have found that these regions are deactivated during mindfulness meditation - which is consistent with the practice's focus on attentional control of mind-wandering episodes (Farb *et al*., 2007; Brewer *et al*., 2011; Lutz *et al*., 2016; Scheibner *et al*., 2017). Importantly, the decrease in DMN activity is more significant during meditation than during other cognitive tasks (Garrison *et al*., 2015), which speaks to the crucial issue of specificity and may be characteristic of the suppression of mind-wandering that can be achieved by trained meditators. It is also worth noting that experiences of flow (Csikszentmihalyi, 1975, 1990), namely states of intense focus in which self-referential processing is inhibited (such as intense practice in expert athletes or jazz improvisation in expert musicians), are also associated with decreased activity in the mPFC (Ulrich *et al*., 2014). Interestingly, psychedelic drugs have been shown to decrease activity in the mPFC and PCC as well (Carhart-Harris *et al*., 2012; Palhano-Fontes *et al*., 2015). These nodes of the DMN have been shown to be more active during various types of self-related stimuli (Northoff *et al*., 2006; Sugiura *et al*., 2008; Qin and Northoff, 2011; Tacikowski *et al*., 2017), self-reflection (Jenkins and Mitchell, 2011; D'Argembeau, 2018) and autobiographical memory retrieval (Cabeza and St Jacques, 2007). A recent study using dynamic causal modeling suggested that self-referential processes are driven by PCC activity and modulated by the regulatory influences of the mPFC (Davey *et al*., 2016).

[3] To be specific, meta-awareness of mind-wandering episodes may crucially involve *de se* thought, such as the thoughts "My mind is wandering" or "I need to refocus my attention on the breath." Here, we are referring to what may happen with experienced meditators when this cycle of mind-wandering and meta-awareness comes to a halt, if only for a brief period, giving way to an episode of thought-free awareness.

Aside from changes in cerebral blood flow in these regions, psilocybin, ayahuasca and LSD have also been consistently linked to decreased functional integrity of the DMN (Carhart-Harris *et al*., 2012, 2016b; Palhano-Fontes *et al*., 2015). Moreover, DMN disintegration was correlated with reports of ego dissolution (Carhart-Harris *et al*., 2016b) and decreased mental time travel to the past (Speth *et al*., 2016). These findings are intriguing, because strong DMN connectivity at rest is associated with increased tendency for mental time travel, in particular spontaneous thoughts about the future (Schacter *et al*., 2007; Godwin *et al*., 2017; Karapanagiotidis *et al*., 2017; Wang *et al*., 2017). This suggests that reports of drug-induced ego dissolution may be related to the experience of decreased self-referential thought and mental time travel, which is also fundamental to the practice of meditation.

While the temporary cessation of self-referential thoughts is one way in which narrative self-consciousness may be altered, it may also be disrupted by a total loss of access to autobiographical memories and self-related beliefs. These two cases are not unrelated, given that the unavailability of personal memories and beliefs precludes the possibility of at least some forms of *de se* thought and mental time travel. However, the experience of losing access to these memories and beliefs might differ from the mere cessation of *de se* thought from a phenomenological point of view. Indeed, anecdotal evidence from narrative self-reports suggests that drug-induced ego dissolution may be related in some cases to reversible retrograde amnesia, specifically regarding abstract information about oneself (i.e., semantic autobiographical memory). For example, one subject responding to an online questionnaire on ego dissolution reported "forgetting that I was a male, a human, a being on Earth - all gone, just infinite sensations and visions," while another stated "I no longer felt human. I didn't remember what a human was" (R.M., unpublished data from an online survey on drug-induced ego dissolution completed by experienced users of psychedelic drugs)[4].

[4] While it is possible that such drug-induced episodes are only partially integrated into autobiographical memory (similarly to dreams), these reports specifically suggest that the episodes themselves may involve a loss of access to autobiographical information.

Interestingly, decreased functional connectivity within the DMN is associated with age-related memory deficits (Damoiseaux *et al*., 2008; Ward *et al*., 2015) and Alzheimer's disease (Greicius *et al*., 2004; Dennis and Thompson, 2014; Dillen *et al*., 2017). Given the link between DMN disintegration (decreased within-network connectivity) and ego dissolution, it is intriguing to speculate that the temporary loss of access to semantic autobiographical information that can occur in the psychedelic state may be mediated by pronounced reductions in DMN integrity. Interestingly, *post-hoc* mediation analyses from Dillen and colleagues revealed that the retrosplenial cortex enables communication between the hippocampus and DMN regions in healthy controls, but not in individuals reporting cognitive decline or diagnosed with prodromal Alzheimer's disease (Dillen *et al*., 2017). Ratings of ego dissolution under LSD have been shown to correlate with decreased resting-state functional connectivity between the retrosplenial cortex and the parahippocampus (Carhart-Harris *et al*., 2016b). If the retrosplenial cortex acts as a gateway between the hippocampal formation and specific DMN regions for memory retrieval, the correlation between this change in connectivity and ego dissolution may be related to a loss of access to autobiographical memories. It is also interesting to note that damage to the retrosplenial cortex has been linked with retrograde amnesia (Valenstein *et al*., 1987; Takayama *et al*., 1991; Gainotti *et al*., 1998; Oka *et al*., 2003), and damage to the hippocampal formation has been associated with both retrograde amnesia (Scoville and Milner, 1957; Squire, 1992; Steinvorth *et al*., 2005) and loss of general world knowledge (Rempel-Clower *et al*., 1996; Bayley *et al*., 2006; Gregory *et al*., 2014).

In summary, narrative aspects of self-consciousness can be radically altered during a specific conscious episode in two ways: through a temporary cessation of self-referential thought and mental time travel, or more dramatically through a temporary loss of access to semantic autobiographical information, resulting in a complete breakdown of one's personal identity. While the former can seemingly be induced both by contemplative practices and by psychedelic drugs, the latter appears to be more specific to psychedelics, and may be related to more pronounced reductions in DMN integrity - which does not appear to be such a reliable feature of meditation.

In the first case, the retrieval of self-related information is effectively reduced, via attentional control in the case of meditation, and perhaps via an involuntary attentional shift in the case of psychedelic states. In the second case, even the dispositional ability to retrieve such information is temporarily impaired, which amounts to a form of reversible amnesia. It is important to note that these alterations of narrative aspects of self-consciousness come in degrees. At low doses of psychedelics or in novice meditators, self-referential spontaneous thoughts and mental time travel are unlikely to disappear entirely for an extended period of time. By contrast, states of deep absorption achieved by advanced meditators or with higher doses of psychedelics are more likely to involve a complete cessation of these thoughts. Similarly, the disruption of *access* to self-related information may be partial or total in different cases. For example, there is a difference between the inability to remember what one has done the day before, the inability to remember one's name, and the inability to remember anything at all about oneself, including that one belongs to the human species (which has been reported, *post-hoc*, with certain doses of some psychedelics). Thus, narrative aspects of self-consciousness may be temporarily disrupted in different ways and to varying degrees by meditation and psychedelics and it is not yet clear whether these different degrees or grades lie on a linear or nonlinear scale.

Disruption of Multisensory Aspects of Self-Consciousness

While self-related thoughts are a paradigmatic example of self-consciousness, it is widely agreed that self-consciousness is not strictly limited to the cognitive domain. In particular, a number of authors have stressed the need to distinguish between the "narrative self," congruent with narrative aspects of self-consciousness outlined in the previous section, and the "minimal" or "embodied" self (Damasio, 1999; Gallagher, 2000; Legrand and Ruby, 2009; Christoff *et al*., 2011; Musholt, 2013; Zahavi, 2014). For example, Gallagher defines the minimal self as "a consciousness of oneself as an immediate subject of experience, unextended in time" (Gallagher, 2000, p. 15), by opposition with the temporal thickness of the narrative self-woven by autobiographical memories and self-projection to the future. Moreover, many authors have insisted on the idea that the minimal self is crucially linked to embodiment and agency, equating this basic form of self-consciousness with an awareness of oneself as an embodied agent (Legrand, 2006; Bayne and Pacherie, 2007; Christoff *et al*., 2011; Seth, 2013). While the distinction between high-level/narrative and minimal/embodied selfhood is helpful as a first pass to clarify the umbrella notion of self-consciousness, it remains somewhat ambiguous and potentially simplistic as such. As we have seen, the "narrative self " is better construed as a family of distinct self-referential processes, which may or may not involve mental time travel, be spontaneous, or recruit abstract semantic information. Likewise, the "embodied" or "minimal" self may be construed as a complex set of somatosensory and agentive aspects of self-consciousness which can come apart in special cases (Blanke and Metzinger, 2009).

At least three constructs that have been related to a basic form of self-consciousness rooted in multisensory processing may be distinguished, namely: (a) the sense of body ownership, namely the alleged sense of "mineness" that one experiences with respect to one's own body or individual limbs; (b) bodily awareness in general, namely the awareness of any bodily sensation, either internal (interoception and proprioception) or external (tactile); and (c) spatial self-location, namely the experience of being located somewhere in space with respect to one's perceived environment.

The Sense of Body Ownership

Body ownership is a controversial notion, as it is not obvious that there is a phenomenology of ownership (a sense of "mineness" over one's body) in daily experience, or how to characterize such phenomenology (Alsmith, 2014; Bermúdez, 2015; De Vignemont, forthcoming). Clinical and experimental evidence suggests that individuals may see body parts or feel tactile sensations originating from them without experiencing them as their own. Indeed, subjects diagnosed with the monothematic delusion known as somatoparaphrenia routinely deny ownership of a limb, despite the fact that nociception and touch may be preserved in the rejected body part (Melzack, 1990; Bottini *et al.*, 2002; see De Vignemont, forthcoming). In the rubber hand illusion, one of the subjects' hands is hidden and stroked synchronously with a rubber hand placed in an anatomically congruent position in front of them (Botvinick and Cohen, 1998); not only do healthy participants report experiencing an illusory ownership over the fake hand, but they also report a loss of ownership over their real hand (Valenzuela Moguillansky *et al.*, 2013). Moreover, a number of physiological measurements appear to indicate that the real limb is temporarily 'disowned' by the body during the illusion, such as a drop in temperature and an increase in histamine reactivity in the participant's real hand (Moseley *et al.*, 2008; Barnsley *et al.*, 2011; but see Rohde *et al.*, 2013). Beyond individual body parts, questionnaire data suggest that ownership over one's *whole body* can be manipulated in so-called full-body illusions induced by synchronous visuotactile stimulation, during which the participant's body - seen in front of them through a head-mounted display - may no longer feel like their own (Ehrsson, 2007; Blanke and Metzinger, 2009).

Although still a matter of controversy, many authors interpret these data as evidence that ordinary conscious experience involves a sense of body ownership that can both be experimentally manipulated and disrupted in clinical cases. Experiencing one's body as one's own would constitute a form of self-consciousness that does not require the possession or deployment of a self-concept, unlike thinking of oneself. Assuming that such a sense of body ownership is indeed ubiquitous at least in the ordinary experience of neurotypical individuals, is there any evidence that it can be altered by meditation and psychedelics? Interestingly, recent studies by Aviva Berkovich-Ohana and colleagues suggest that mindfulness meditation can indeed induce a loss of body ownership (Dor-Ziderman *et al.*, 2013, 2016; Ataria *et al.*, 2015). Ataria and colleagues studied a single highly experienced meditator "S" (with around 20,000 h of practice) trained in the Satipathana and Theravada Vipassana traditions, who was reportedly able to voluntarily induce a state in which basic aspects of self-consciousness appeared to fade away. In particular, S described the dissolution of the sense of body ownership in a series of open-ended interviews following the methodological principles of the microphenomenological interview technique, designed to elicit fine-grained reports of subjective experience while minimizing potential for confabulation (Petitmengin, 2006; Petitmengin and Lachaux, 2013). S reported that in the altered state of consciousness he achieved through meditation "there really isn't any [sense of ownership]. It's a feeling of dissolving. [It is] hard to distinguish between senses in the body and senses outside [sic]... There is no sense of mine [and] there is no sense of me" (Ataria *et al.*, 2015, Supplementary Material). While evidence from single-subject studies should be treated as tentative and interpreted with caution, Dor-Ziderman and colleagues also tested 12 long-term mindfulness meditators in a neurophenomenological study combining magnetoencephalogram (MEG) recording and first-person reports (Dor-Ziderman *et al.*, 2013). Participants were instructed to voluntarily induce a "selfless" mode of awareness characterized as "momentary phenomenal experience free of the sense of agency and ownership" (Dor-Ziderman *et al.*, 2013, p. 3). Subjective reports were analyzed and grouped in categories validated by 12 naïve referees. Four reports were grouped in the category of experiences lacking a sense of ownership, including the following descriptions: "I understood that it was just a sensation, it was not the hand itself… there was a deep thought that all this was not mine" (subject 9); "it was emptiness, as if the self-fell out of the picture. There was an experience but it had no address, it was not attached to a center or subject" (subject 12); "it was to be aware of the body, the sensations, pulse, location of limbs, sounds and sights - to be only a witness to all this" (subject 14) (Dor-Ziderman *et al.*, 2013, p. 6).

There are also many reports of depersonalization-like experiences induced by psychedelics, suggesting that the sense of body ownership can be pharmacologically manipulated (Guttmann and Maclay, 1937; Savage, 1955; Von Mering *et al.*, 1955; Sedman and Kenna, 1964; Studerus *et al.*, 2011). Reports of drug-induced ego dissolution frequently include descriptions of a loss of ownership over one's body (e.g., "I felt disconnected from my physical being, my body"; "[I] looked down at my hand and didn't feel anything that would indicate that this was my hand I was looking at"; R.M., unpublished data from online survey). An intriguing hypothesis is that top-down constraints on body representation are loosened in the psychedelic state. In the rubber hand illusion, for example, it has been hypothesized that the high-level prior probability that one's actual hand is truly one's own is decreased (Limanowski and Blankenburg, 2013; Apps and Tsakiris, 2014). There is preliminary evidence for a weakening of top-down perceptual priors in the psychedelic states, as evidenced by reduced binocular rivalry switching rate and occasional phenomenal fusion of rival images under psilocybin and ayahuasca (Frecska *et al.*, 2003; Carter *et al.*, 2007), as well as reduced susceptibility to the "hollow mask" illusion (unpublished result of Torsten Passie's hollow mask study at the Hannover Medical School in Germany). In addition, a recent study showed that LSD attenuates top-down suppression of prediction error in response to surprising auditory stimuli, as measured by mismatch negativity in the auditory oddball paradigm (Timmermann *et al.*, in press). It is possible that a similar disruption of top-down processing of somatosensory stimuli plays a role in the modulation of body ownership by psychedelics (see also Swanson, 2018 for a discussion of the effects of psychedelics on top-down processing).

Thus, assuming that there is a phenomenology of body ownership in ordinary experience, available evidence from open-ended interviews and self-report questionnaires tentatively suggests that it can go missing during certain conscious states induced by meditation and psychedelics - not only for specific body parts but also for the whole body. However, more evidence is needed to confirm this hypothesis, as well as a rigorous definition and measurement of the sense of body ownership.

Bodily Awareness

Bodily awareness can be defined as the conscious awareness of bodily sensations in general, including tactile, proprioceptive and interoceptive stimuli. A number of authors have argued that bodily awareness constitutes a form of self-consciousness, in part because it grounds self-ascriptions that are immune to error through misidentification (Bermúdez, 2011; De Vignemont, 2011). When one feels pain, for example, one cannot be wrong about *who* is in pain; generally, bodily sensations are said to be immune to error through misidentification insofar as the only body that one can have access to through them is one's own. This kind of consideration has led some philosophers to argue that bodily awareness constitutes a basic form of self-consciousness through which an embodied subject is directly conscious of the bodily self (Evans, 1982; Cassam, 1997; Bermúdez, 2011). In recent years, a similar idea has emerged within neuroscience with a particular focus on interoception, the awareness of internal bodily sensations such as cardiac, respiratory and gastric signals. It has been argued that interoceptive awareness grounds a core sense of self in normal experience, anchoring oneself in one's body (Damasio, 1999; Craig, 2002; Seth, 2013; Tsakiris, 2017). It should be noted that this idea does not necessarily rest on the hypothesis that there is a specific phenomenology of body ownership, although it is not always easy to disentangle the claim that one's body is experienced as one's own from the claim that one's bodily sensations underlie a consciousness of oneself as a bodily subject. The distinction of these two claims turns on the clarification of their theoretical commitments. Here, we will leave this issue aside, and assume that bodily awareness constitutes a basic form of self-consciousness, whether or not it is associated with a specific phenomenology of ownership.

Can meditative practices and psychedelics induce a partial or complete loss of bodily awareness? Given the focus of many meditation practices on bodily sensations, either through open awareness of all present moment sensations (in open monitoring) or through focal awareness of the breath (in focused attention), one would not expect bodily awareness to fade away during meditation practice. The meta-analytic cluster of activation of the insular cortex during OM, FA, and LK reported in the previous section (Fox *et al.*, 2016) also suggests that bodily awareness is central to these meditation practices, given that the insula is an important hub for the processing of interoceptive signals (Critchley *et al.*, 2004; Craig, 2009; Simmons *et al.*, 2013). Nonetheless, there is preliminary evidence that bodily awareness can be reduced in certain forms of mindfulness meditation, at least for highly experienced practitioners. For example, subject S from Ataria and colleagues' study reported that in the "selfless" altered state of consciousness voluntarily achieved through meditation, bodily sensations were "almost invisible" and reduced to a subtle and indistinct background presence: "there is a sense of something happening, it is very hard to tell if there is a sense of body, it is more in the background... a sense of body-ness, but it's so spread... I am not dead; there is a kind of very light sense of body in this experience" (Ataria *et al.*, 2015, Supplementary Material). In their analysis of the same data, Dor-Ziderman and colleagues comment that "even when the [sense of boundaries] disappears, a minimal level of dynamic proprioception continues to exist: there remains a sense that there is a body without any experience of [a sense of boundaries]" (Dor-Ziderman *et al.*, 2016, p. 3).

It is debatable whether proprioceptive awareness was retained in this state, given the difficulty that subject S had in locating his bodily sensations on a body-part-centered spatial frame of reference ("I can't tell you at all which [hand] is right and which is left. I don't know", Ataria *et al.*, 2015, Supplementary Material). Nonetheless, it is plausible that some degree of *interoceptive* awareness was preserved, which is consistent with the fact that the body was merely experienced as some kind of vague background presence. Berkovich-Ohana and colleagues also found that experienced mindfulness meditators could significantly inhibit awareness of bodily sensations during their practice (Berkovich-Ohana *et al.*, 2013): "The experience of the body faded. There was a sense of body in the background, not in front of consciousness" (subject 4); "A wide experience with un-defined boundaries. A sense... that I am dissolving, my body dissolving." (subject 5); "There was a vanishing of bodily sensations" (subject 11).

While it remains unclear whether bodily awareness can completely disappear during meditation, there is evidence that subjects can lack any awareness of their body and of specific bodily sensations in altered states induced by psychedelic substances. As previously mentioned, early studies with mescaline and LSD reported depersonalization-like effects which occasionally involved a loss of bodily awareness (Guttmann and Maclay, 1937; Savage, 1955; Von Mering *et al.*, 1955; Sedman and Kenna, 1964). In the psychometrically validated 5D-OAV questionnaire commonly used to assess the subjective experience of altered states of consciousness (Studerus *et al.*, 2010), healthy participants score rather high on the "disembodiment" factor, which includes the item "it seemed to me as if I did not have a body anymore," after administration of psilocybin (Kometer *et al.*, 2012; Bernasconi *et al.*, 2014; Preller *et al.*, 2016; Pokorny *et al.*, 2017) and LSD (Schmid *et al.*, 2015; Carhart-Harris *et al.*, 2016a,b; Kraehenmann *et al.*, 2017; Liechti *et al.*, 2017; Preller *et al.*, 2017b). The strength of the subjective effects of LSD (as measured by the mean score on the 5D-ASC questionnaire) was found to correlate with the magnitude of increase in functional connectivity in a somatomotor network including the primary motor and sensorimotor cortices, the caudal premotor cortex and the superior parietal lobule (Preller *et al.*, 2017a).

In a recent neuroimaging study of DMT, a drug whose short lasting subjective effects are more intense and immersive than those of psilocybin or LSD, almost all participants reported a loss of awareness of their body for several minutes during the peak of the experience in post-hoc microphenomenological interviews: "I lost awareness of gravity and awareness of my body" (Timmermann *et al.*, in preparation). There is also considerable anecdotal evidence from narrative reports that psychedelics can radically disrupt bodily awareness, an effect often associated with the dissolution of the sense of self (Millière, 2017): "It felt as if 'I' did no longer exist. There was purely my sensory perception of my environment, but sensory input was not translated into needs, feelings, or acting by 'me'. Also, I felt disconnected from my physical being, my body" (R.M., unpublished data from online survey). Anecdotal evidence regarding the dramatic effects of 5- MeO-DMT suggests that this drug may be particularly effective at suppressing bodily awareness, although controlled studies of these effects are needed[5].

[5] See section Spatial self-location below for anecdotal reports and questionnaire data regarding states induced by 5-MeO-DMT.

Thus, it seems that certain meditation practices may inhibit awareness of bodily sensations, reduced in some cases to a mere background interoceptive awareness, while psychedelic substances (DMT and 5-MeO-DMT in particular) may completely suppress awareness of the body. Sensory deprivation is likely to be a factor in this reduction of bodily awareness: meditators are usually sitting in silence with eyes closed, while participants of neuroimaging studies of psychedelics are often lying down in supine position with a blindfold. The lack of somatosensory and motor feedback in these states may play an important role in the loss of bodily awareness. Interestingly, two recent findings emphasize the influence of sensory deprivation on the plasticity of body representation: short-term visual deprivation has been shown to lead to significantly larger proprioceptive drift in the rubber hand illusion (Radziun and Ehrsson, 2018), while audio-visual sensory deprivation has been found to degrade the boundary of the whole body peripersonal space (Noel *et al.*, 2018). These results suggest that sensory deprivation enhances the flexiblity of body representation, and could facilitate the disruption of bodily awareness in meditation and psychedelic states.

Finally, it is important to note that psychedelic drugs, just like some styles of meditation, may also *increase* awareness of the body, especially at lower doses associated with salient and unusual bodily sensations (see section Toward a multidimensional model of altered self-consciousness below). Finally, it can also be observed that drug-induced states are not the only known altered states of consciousness in which bodily awareness can fade away altogether; there is good evidence that this can also be the case in so-called "bodiless" dreams (LaBerge and DeGracia, 2000; Cicogna and Bosinelli, 2001; see Windt, 2010, 2015; Occhionero and Cicogna, 2011) and "asomatic" out-of-body experiences (Alvarado, 2000; see Metzinger, 2013).

Spatial Self-Location

A third notion associated with a minimal form of self-consciousness rooted in multisensory integration is spatial self-location (Blanke and Metzinger, 2009; Serino *et al.*, 2013; Maselli, 2015). It has been argued that perceptual experience, and visual experience in particular, is *self-locating* (Cassam, 1997; Noë, 2005; Schwenkler, 2014). This idea typically combines two claims: first, in virtue of being structured by an egocentric frame of reference[6], visual experience represents the location of the point of origin of this reference frame relatively to environmental landmarks; secondly, the location of this point of origin is represented as the location of the subject (i.e., where *I* am located with respect to objects in the visual scene). This analysis may be extended to other sensory modalities whose content presumably has a perspectival structure centered onto a single point of origin, such as auditory perception (Coleman, 1963; Zahorik *et al.*, 2005; Kolarik *et al.*, 2016).

[6] On the notion of egocentric frame of reference, see Klatzky (1998).

Whether perspectival structure always entails *self-locating* content - namely a representation of the location of the origin as the location of the *subject* - is a matter of debate (Alsmith, 2017). Some authors have argued that self-locating content also requires the ability to act upon objects perceived in one's environment (Brewer, 1992; Schellenberg, 2007; Alsmith, 2017). Nonetheless, it is generally agreed that ordinary perceptual experience has self-locating content. In other words, one normally experiences oneself as located at a certain distance with respect to objects perceived in one's environment. Interestingly, both questionnaire data and behavioral measurements suggest that self-location can be manipulated in full-body illusions, such that subjects may feel located outside of their own body (Ehrsson, 2007; Guterstam *et al.*, 2015) or closer to the virtual avatar over which they feel ownership during the illusion (Lenggenhager *et al.*, 2007, 2009; Ionta *et al.*, 2011). Similarly, out-of-body experiences and heautoscopic phenomena of clinical origin, in which subjects hallucinate seeing their own body from the outside, appear to involve a shift of self-location (often to an elevated position) associated with a hallucinatory visuospatial perspective (Blanke and Arzy, 2005; Blanke and Mohr, 2005).

Such experimental and clinical evidence isolating spatial self-location as a dissociable component of ordinary experience has led researchers to claim that it constitutes an important aspect of bodily self-consciousness (Blanke and Metzinger, 2009; Blanke *et al.*, 2015), and even a minimally sufficient condition for self-consciousness (Metzinger, 2013; Windt, 2015). Interestingly, there is evidence that both meditation and psychedelics may radically disrupt the experience of being located somewhere in space; moreover, this disruption appears to be often associated with reports of "selflessness" or "ego dissolution," suggesting that spatial self-location is indeed a basic and important building block of self-consciousness. The highly experienced mindfulness meditator studied by Ataria and colleagues described the selfless state he reportedly achieved for the experiment in the following terms: "it's like falling into empty space... and a sense of dissolving... and there really isn't a center... I don't have any kind of sense of location... I have no idea where I am in stage three, it's all background, I'm not there basically, just world, so there's no real location at all in stage three. It's very minimal, almost nothing... When there's no boundary, there's no personal point of view, it's the world point of view, it's like the world looking, not [me] looking, the world is looking." (Ataria *et al.*, 2015, Supplementary Material). As Dor-Ziderman and colleagues comment, in this meditation-induced altered state of consciousness, it seems that "the sense of orientation in space is lost altogether" (Dor-Ziderman *et al.*, 2016, p. 3). In another neuroimaging study of long-term mindfulness meditation practitioners, Berkovich-

Ohana and colleagues found that some of them were able to induce what they described as a state of "spacelessness," reported in the following terms: "the center of space became endless, without a reference point in the middle" (subject 4); "it was a sense of spaciousness, boundlessness... there was no clarity where the center is and where is the periphery. There was no quality of border" (subject 11) (Berkovich-Ohana *et al.*, 2013).

Likewise, there is converging evidence from subjective reports that psychedelic drugs can induce a loss of spatial self-location, associated to loss of boundary between self and world and a feeling of unity with everything (Millière, 2017): "I felt myself mold into the world around me... ," "My mind started to blend with everything" (R.M., unpublished data from online survey). On the psychometrically-validated 5D-ASC questionnaire, subjects score high on the factor related to "experience of unity" after administration of LSD (Schmid *et al.*, 2015; Carhart-Harris *et al.*, 2016a,b; Kraehenmann *et al.*, 2017; Liechti *et al.*, 2017; Preller *et al.*, 2017b) and to a slightly lesser extent psilocybin (Kometer *et al.*, 2012; Bernasconi *et al.*, 2014; Preller *et al.*, 2016; Pokorny *et al.*, 2017). This factor includes the items "it seemed to me that my environment and I were one" and "everything seemed to unify into oneness". Moreover, studies using custom questionnaire items have also measured high scores for "I experienced a sense of merging with my surroundings" after administration of psilocybin and LSD (Muthukumaraswamy *et al.*, 2013; Carhart-Harris *et al.*, 2016b; Schartner *et al.*, 2017). A recent online survey on the effects of 5-MeO-DMT with 515 participants also found that the overwhelming majority of respondents scored positively on items of the Mystical Experience Questionnaire corresponding to "Loss of your usual sense of space" (95% of respondents), "Loss of usual awareness of where you were" (88% of respondents) and "Being in a realm with no space boundaries" (87% of respondents) (Davis *et al.*, 2018).

In addition to questionnaire data from controlled studies, there is a large amount of anecdotal evidence from online narrative reports that DMT and 5-MeO-DMT can induce a loss of self-location: "at the time I didn't know where it was, or where I was... I didn't know what had happened before this point, in-between, sideways, up, down or anywhere" (DMT, report from www.dmt-nexus.me), "I was the universe, I was everywhere and nowhere, everything and nothing all at the same time" (5-MeO-DMT, report #49690 from Erowid.org), "The feeling was very cosmic, of oneness with everything" (5-MeO-DMT, report #78485 from Erowid.org), "an immediate complete dissolution of any identity and a merging into the Oneness, timeless, pure awareness and light energy of the Universe... Similar in some ways with a previous *Samadhi* meditation experience" (5-MeO-DMT, report #5804 from Erowid.org; see below on *Samadhi* meditation). A similar phenomenological report can be found in a (non-academic) monograph on 5-MeO-DMT: "I was completely disconnected somatically, unable to locate or feel my body... unable to locate myself - or anything else - anywhere in particular. I had no body, not even the slightest semblance of a dream-body or mental-body, and I had absolutely no sense of where I was" (Masters, 2005). Taken at face value, these reports suggest that psychedelic drugs can induce experiences which may have perceptual content without spatial - or at least self-locating - content. Although narrative reports from online databases offer at best anecdotal evidence, their convergence with questionnaire data from multiple controlled studies suggests that they may be taken into consideration to inform hypotheses about the effect of psychedelics on the sense of self-location.

We note that these reports of meditative and psychedelic experiences lacking spatial self-locating content might be reminiscent of reports of conscious episodes during dreamless sleep, which allegedly lack any form of self-consciousness and spatial content (Thompson, 2014a; Windt *et al.*, 2016). Jennifer Windt has argued that such dreamless sleep experiences might be characterized by "pure subjective temporality," conceived as the minimal phenomenology of temporal self-location ("nowness") and duration (Windt, 2014). If such states do exist, we can plausibly hypothesize that they might also be induced by meditation and psychedelic drugs, on the basis of the preliminary evidence discussed in this section. However, we also note that many reports of drug-induced ego dissolution, especially with 5-MeO-DMT, insist on the *timeless* character of the experience, described as a complete loss of the sense of temporal duration. The aforementioned online survey on the effects of 5-MeO-DMT found that the overwhelming majority of respondents scored positively on items of the Mystical Experience Questionnaire corresponding to "Loss of your usual sense of time" (97% of respondents), "Experience of timelessness" (90% of respondents), "Sense of being outside of time, beyond past and future" (89% of respondents) and "Feeling that you experienced eternity or infinity" (88% of respondents) (Davis *et al.*, 2018). Interestingly, some mindfulness meditators have been reported to achieve a similar disruption of the phenomenology of duration through their practice (Berkovich-Ohana *et al.*, 2013). Thus, we tentatively suggest that some drug-induced and meditative states might lack both *spatial* and *temporal* self-locating content.

From a neurophysiological point of view, it is interesting to note that the intensity of drug-induced ego dissolution reported by participants under LSD was found to correlate with the magnitude of increased functional connectivity in the bilateral insular cortex and the temporoparietal junction (Tagliazucchi *et al*., 2016). Meanwhile, Dor-Ziderman and colleagues found that the transition from minimal self-consciousness to a "selfless" state characterized by a loss of body ownership and self-location in experienced meditators was correlated with a decrease in beta power in the temporoparietal junction (Dor-Ziderman *et al*., 2016). These findings are intriguing since there is evidence from neuroimaging studies of out-of-body experiences and full-body illusions that the temporoparietal junction plays a role in processing spatial self-location (Blanke and Arzy, 2005; Ionta *et al*., 2011; Blanke, 2012). Given that a number of intracranial EEG and MEG studies have suggested that beta oscillations encode top-down modulations of predictions (Bauer *et al*., 2014; Michalareas *et al*., 2016; Sedley *et al*., 2016), it is intriguing to speculate that decreased beta power in the TPJ may relate to weakened top-down constraint on multisensory processing underlying self-location. In addition, the insular cortex is associated with the integration of interoceptive information (Craig, 2009; Simmons *et al*., 2013), and may play an important role in body awareness and ownership (Aspell *et al*., 2013; Seth, 2013; Suzuki *et al*., 2013). Thus, while the modulation of beta oscillatory power and functional connectivity in the temporoparietal junction in some psychedelic and meditative states may be linked to the disruption of spatial self-location, the modulation of functional connectivity in the insula during drug-induced ego dissolution might be specifically related to the loss of bodily awareness. However, more data is needed to confirm these hypotheses.

To conclude this section, it should be noted that our overview of narrative and multisensory aspects of self-consciousness has left out the notion of the sense of agency, typically defined as the experience of being in control of one's actions (Haggard, 2017). There are three reasons for this omission aside from spatial constraints. Firstly, the sense of agency is an ambiguous concept, which has been construed both as a feeling of control over one's bodily movements allegedly produced by comparator mechanisms, and as a feeling of control over the production of one's thoughts. Secondly, there is little available evidence regarding how the sense of agency, in either construal, may be modulated by meditation and drug-induced states. Although experiences of self-loss with both psychedelics and meditation typically occur when subjects are immobile (in seated or supine position), increased voluntary control over one's breathing in certain styles of meditation could modulate the sense of bodily agency. Further evidence could be provided by measures of intentional binding during meditation and psychedelic states. Likewise, one could expect attentional control of spontaneous thoughts in meditation to have an effect on the sense of cognitive agency, if this notion is valid. Finally, it is worth mentioning that the claim that voluntary movements and thoughts are ordinarily accompanied by a pervasive sense of agency has recently come under criticism (Grünbaum, 2015; Grünbaum and Christensen, 2017; Parrott, 2017). According to a more deflationary account, there is no special phenomenology of agency in ordinary experience[7].

Pure consciousness, non-dual awareness and total selflessness

In this section, we examine in more detail some meditation practices which explicitly aim at a dissolution of all aspects of self-consciousness, and consider how the resulting global states of consciousness compare to drug-induced states. More specifically, we focus on practices targeting the subject-object dichotomy which allegedly structures ordinary conscious experience, in order to reach a state of "non-dual awareness" (NDA; Josipovic, 2010), or even induce a state of consciousness supposedly empty, i.e., devoid of any content ("pure consciousness"). It is an open question whether NDA differs from pure consciousness, and in what respect; but a critical examination of descriptions of these states suggests that both may involve a dramatic form of self-loss characterized by a dramatic inhibition of the dimensions of self-consciousness outlined in the previous section.

[7] In a predictive coding framework, in particular, it is reasonable to assume that the violation of expectations regarding one's bodily movements, rather than the match between those expectations and sensory feedback, modulates phenomenology. Accordingly, prediction error signals might give rise to a feeling of alienation from one's action, but the absence of prediction error signals should not be associated with a positive feeling of agency (Fletcher and Frith, 2009; although see Hohwy, 2016 for a predictive coding account of the sense of agency). This explanatory model can be extended to thoughts to account for schizophrenic thought insertion without appealing to a loss of the sense of agency (Parrott, 2017). However, it should be acknowledged that the existence of a positive phenomenology of agency might be more in line with the active inference framework, according to which organisms minimize prediction error not only by updating prior expectations, but also through

action (Friston, 2013). Within this framework, the sense of agency may result from the process of modeling the effects of the selective sampling of sensations through action (Limanowski and Blankenburg, 2013).

Non-dual Awareness

Non-dual awareness meditation (NDA) refers to a family of practices which can be found in several Eastern contemplative traditions, including Dzoghen and Mahāmudrā within Tibetan Buddhism, and Advaita Vedanta and Kashimiri Shaivism within Hinduism (Josipovic, 2010; Dunne, 2011). NDA meditation rests on three core assumptions: (a) ordinary experience is "dual" or dichotomous, insofar as it is structured around a subject-pole and an object-pole; (b) this subject-object dichotomy is illusory, because conscious awareness as such is not fundamentally dual; (c) it is possible, through the practice of NDA meditation, to dispel this illusion and directly experience conscious awareness as non-dual. All of these assumptions are worth discussing. The first assumption, in particular, requires clarification. It is rather uncontroversial that all conscious mental states have a subject of experience, insofar as "an experience is impossible without an experience" (Frege, 1956, p. 299, translation modified). This is merely a metaphysical requirement of conscious experience[8]. However, assumption (a) goes further in claiming that the phenomenal character of conscious experience is itself structured by a subject-object dichotomy.

There are at least two ways to understand this claim. As we have seen in the previous section, a number of components of ordinary experience can be related to a form of self-consciousness - including self-related thought, body ownership, bodily awareness and spatial awareness. One can claim that conscious experience normally involves a background awareness of oneself which is reducible to one or several of these components (Damasio, 1999; Blanke and Metzinger, 2009; Bermúdez, 2011; Seth, 2013). According to this reductionist interpretation, ordinary consciousness is structured by a subject/object dichotomy.

There are at least two ways to understand this claim. As we have seen in the previous section, a number of components of ordinary experience can be related to a form of self-consciousness - including self-related thought, body ownership, bodily awareness and spatial awareness. One can claim that conscious experience normally involves a background awareness of oneself which is reducible to one or several of these components (Damasio, 1999; Blanke and Metzinger, 2009; Bermúdez, 2011; Seth, 2013). According to this reductionist interpretation, ordinary consciousness is structured by a subject/object dichotomy insofar as we are normally aware of ourselves via thought, perception and bodily sensations in addition to being aware of external objects. A second interpretation holds that there is a form of *sui generis* self-awareness in experience which is irreducible to the cognitive, bodily and spatial features of experience: "being presented with something necessarily involves being pre-reflectively and pre-conceptually aware of being the subject to whom something is presented" (Nida-Rümelin, 2017, p. 66; see also Strawson, 1999; Kriegel, 2009; Zahavi, 2014; Guillot, 2017). According to this second interpretation, the seemingly dichotomous nature of experience does not rest on a specific kind of self-representing content, but on the very nature of conscious representation in general, which is structured by an implicit distinction between the represented objects and the subject to whom those objects are presented. In similar fashion, Evan Thompson has argued that ordinary experience is infused with a sense of mineness such that every thought, emotion, perception or sensation is experienced *as one's own*, and has also suggested that this feature can disappear during meditation (Thompson, 2014b, p. 362).

On both of these interpretations, conscious experience is structured by a subject-object dichotomy insofar as it involves an awareness of oneself in addition to the awareness of external objects. Accordingly, non-dual awareness states can be construed as conscious states which lack the background self-awareness normally present in experience. However, a core assumption of non-dual awareness meditation practices is that the subject-object dichotomy supposedly found in ordinary experience is illusory, in line with the so-called "no self" doctrine of Buddhism (*anātman* in Sanskrit or *anattā* in Pali). Thus, non-dual awareness practice is supposed to reveal that the putative phenomenological distinction between oneself and one's experience of the external world is ultimately an illusion[9].

---

[8] Importantly, the notion of subject of experience at play in this claim is very thin - it does not carry more substantial commitments about subjects being Cartesian substances enduring in time, or identical to organisms or parts of organisms. Rather, the claim merely stems from conceptual analysis of the notion of experience. Accordingly, a thin subject of experience is simply the bare locus of an experience; an experience cannot occur without there being something it is like for such a thin subject to have it, and conversely a thin subject cannot exist without the occurrence of an experience whose subject it is (see Peacocke, 2014; Strawson, 2017). One might wonder whether this supposedly uncontroversial claim is compatible with the Buddhist "no self " doctrine. This is a difficult question, not least because there are several interpretations of the "no self " doctrine. However, common interpretations of the "no self " view articulate two claims: a metaphysical claim, according to which there is no such thing as *the self* construed as a substance or enduring entity; and a phenomenological claim, according to which the sense of self is not a necessary and invariant feature of experience (see MacKenzie, 2016). Both points are compatible with the minimal claim that all experiences have subjects of experiences, in the thin sense outlined above.

While this general idea appears to be consistent with recent proposals regarding the notion of non-dual awareness, it is not always clear which of the two interpretations outlined above is favored. For example, Wolfgang Fasching has argued that in normal experience, subjects are aware of their body and location in addition to objects of the external world, which suggests that he favors the reductionist interpretation of the subject/object dichotomy. In the same vein, he suggests that self-consciousness is rooted in the identification of oneself with "certain configurations of experienced contents as opposed to others" (Fasching, 2008, p. 476), which is also consistent with the first interpretation. However, he goes on to argue that "in perception I am necessarily co-conscious of myself " (Fasching, 2008, p. 472), because the subject/object polarity is built in all conscious representational states. He further claims that some meditation practices can reveal that "I am not something 'inner' as distinct from external objects" and that "there is no 'I' to which things are given, there is just the event of givenness" (Fasching, 2008, p. 478). In this context, meditation is conceived as a way of becoming aware of consciousness as such, without the illusory distinction between the subject and the objects of experience. Fasching cites a central text of the Vedic tradition, the Māṇḍūya Upaniṣad, which describes the state of non-dual awareness reached through meditation as one in which the subject is "not conscious of the internal world, nor conscious of the external world" (Deutsch, 1969, p. 62). Similarly drawing on the Vedic tradition, Miri Albahari suggests that non-dual awareness meditation involves "a direct realization that consciousness... is ownerless" (Albahari, 2010, p. 104).

[9] Note that this further assumption does not sit well with the proposals of Nida-Rümelin and Zahavi, according to whom "pre-reflective self-awareness" or "self-givenness" is a necessary component of all conscious experiences in general.

These descriptions seem consistent with the second interpretation above: in ordinary conscious states, subjects have a sense that all of their experiences are *theirs*, *given to them*, or *owned by them*; in turn, this introduces an artificial distinction between oneself as the subject of experience and the experiences themselves; finally, trained meditators can dispel this illusion by becoming aware of consciousness itself as a non-dual process. Although we cannot discuss this proposal at length within the scope of this article, it is worth underlining that it rests on a controversial picture of ordinary experience. Indeed, the idea that consciousness is normally infused with a special sense of phenomenal mineness or awareness of oneself as the owner of one's experiences is far from obvious and has been met with a number of objections (see Howell and Thompson, 2017; O'Conaill, 2017; Chadha, 2018; McClelland, forthcoming; Wu, forthcoming).

By contrast, the first interpretation of non-duality outlined above seems consistent with the evidence presented in the previous section: the inhibition of self-related thoughts, body ownership, bodily awareness and self-location should entail a blurring or dissolution of the boundary between self and world, and the associated "unitive experience" - identified by Walter Stace as the core feature of so-called "mystical-type experiences" (Stace, 1960). Although narrative and multisensory aspects of self-consciousness are not illusory as components of ordinary experience, their transient cessation in meditation or drug-induced states may be interpreted as revealing that their association with a more substantial notion of selfhood is fallacious (see also Metzinger, 2003; MacKenzie, 2016; Letheby and Gerrans, 2017). It is worth noting, however, that classic accounts of non-dual awareness in the Buddhist and Hindu traditions emphasize its reliance on the loss of narrative aspects of self-consciousness more than the loss of multisensory aspects. Non-dual Mahāmudrā a practice, for example, instructs students to "drop thoughts of past, present and future and release the mind into its natural state of clear, non-conceptual awareness" (Dunne, 2011, p. 81). Consequently, it is possible that global states of consciousness reached through NDA meditation may preserve some awareness of bodily sensations[10].

[10] One possibility, in line with the distinctions outlined in section Alterations of self-consciousness induced by meditation and psychedelics, is that NDA states may involve a minimal awareness of bodily sensations (e.g., interoceptive signals) without a sense of body ownership (an awareness of these sensations *as one's own*).

In summary, we have suggested that the notion of NDA states can be understood in two different ways. According to the first interpretation, they are conscious states in which both narrative and perhaps multisensory aspects of self-consciousness are radically disrupted, such the distinction between oneself and the external world no longer has an experiential basis. According to the second interpretation, ordinary conscious states involve a minimal form of self-awareness which is not tied to any specific content, but to a special sense of "self-givenness" or "mineness" built in normal experience; in NDA states, this feature supposedly goes missing, such that subjects become aware of consciousness itself as an ownerless process. While the second interpretation rests on a controversial assumption about normal experience, the first is consistent with the evidence presented so far regarding the phenomenology of alleged "selfless" states in meditation and drug-induced states[11].

[11] To be clear, we are not denying that actual descriptions of NDA states from contemplative scholars may seem more consistent with the second interpretation, if they are taken at face value. Rather, we suggest that such an interpretation rests on an account of the phenomenology of ordinary experience which is at best ambiguous and at worst implausible - in so far as it seems to postulate the ubiquity of a *sui generis* "sense of mineness." Accordingly, we put forward an interpretation of NDA states which appears to be more consistent with an evidence-based account of the multiple dimensions of the sense of self, as described in section Alterations of self-consciousness induced by meditation and psychedelics. It is also worth emphasizing that our purpose in this article is *not* to engage in the exegesis of historical sources from the Buddhist and Hindu traditions, but to offer a critical discussion of available evidence regarding global states of consciousness described as involving a dramatic loss of the sense of self.

Although there have been few neuroimaging studies of NDA meditation, the available evidence is intriguing. In the resting state, activity in the default-mode network has been found to be negatively correlated with activity in a set of regions commonly recruited in attention-demanding tasks, in particular the sensory (Golland *et al*., 2007), dorsal attention network and fronto-parietal control network (Greicius *et al*., 2003; Fox *et al*., 2005; Uddin *et al*., 2009; Chai *et al*., 2012; Carbonell *et al*., 2014). A similar pattern of anticorrelation has been reported during mindfulness meditation (Brewer *et al*., 2011; Kilpatrick *et al*., 2011; Hasenkamp *et al*., 2012), and there is some preliminary evidence of increased anti-correlation between the DMN and a task-positive network during focused attention meditation compared to the resting state (Josipovic *et al*., 2012). However, Josipovic and colleagues found that this anticorrelation was significantly *decreased* during NDA meditation compared to both focused awareness meditation and the resting state (Josipovic *et al*., 2012; Josipovic, 2014). It is worth noting that a similar pattern of increased correlation between the DMN and the habitually anti-correlated networks has been observed during various other forms of meditation, such as mantra recitation (Berkovich-Ohana *et al*., 2015) as well as choiceless-awareness, loving-kindness and concentration in experienced meditators compared to novice meditators (Brewer *et al*., 2011). Thus, it is questionable that this change of connectivity is unique to NDA meditation. Interestingly, a similar decrease of the anticorrelation between the DMN and a task-positive network has been observed after administration of psilocybin, and was hypothesized to correlate with decreased separatedness between internally and externally focused states (Carhart-Harris *et al*., 2013). Although this hypothesis is speculative, it is possible that conscious states induced through NDA meditation have a lot in common with certain states of "ego dissolution" induced by psychedelics from a phenomenological point of view. Before discussing this potential convergence, we will assess how NDA may relate to so-called "pure consciousness."

Pure Consciousness

The notion of pure consciousness seems to originate in Stace (1960, p. 86), who applies it to mystical experiences. A purely conscious state is characterized by "an 'emptying out' by a subject of all experiential content and phenomenological qualities, including concepts, thoughts, sense perception, and sensuous images" (Gellman, 2017). States which have been qualified as purely conscious include experiences reached through certain forms of meditation (Nash and Newberg, 2013) and mystical experiences (Stace, 1960; Shear, 1994).

There has been considerable debate about whether purely conscious states are even possible. Some have argued that they are impossible because one cannot be conscious without being conscious of anything at all (Bayne, 2007, p. 16) or because one cannot have episodic memory of a state devoid of experiential content (Bagger, 1999, p. 102; Gennaro, 2008). Others have argued that pure consciousness is not ruled out by logical or phenomenological considerations (Woodhouse, 1990; Shear, 1994), and that we might even find empirical evidence of pure consciousness in contemplative practices (Koch, 2004; Baars, 2013; Metzinger, 2013; Nash and Newberg, 2013) or dreamless sleep (Windt *et al*., 2016). Note that this apparent disagreement could be a mere verbal dispute, because there is an important ambiguity in the notion of a conscious mental state devoid of any content. Indeed, "content" might refer here to *representational* or *phenomenal* content.

Although controversial, the hypothesis that some conscious mental states lack *representational* content has been defended on the ground that states such as moods, pain or orgasm which do not seem to represent anything (Rey, 1998; Kind, 2007; Aydede, 2009). This is in fact the basis of a prominent objection to representationalism, the thesis that all phenomenally conscious states have representational content, or in its stronger version that the phenomenal character of all conscious mental states is wholly constituted by their representational content. But representational contentlessness is presumably not what proponents of pure consciousness have in mind, as they suggest that purely conscious states lack "all determinate phenomenological contents... whatsoever" (Shear, 1994, p. 320). Thus, the strict definition of a purely conscious state would be a conscious mental state lacking phenomenal character. However, this definition cannot be taken literally if we are talking about phenomenal consciousness: by definition, a phenomenally conscious mental state is a mental state such that there is something it like for a creature to be in it (Nagel, 1974), and if there is something it is like to be in a mental state then the mental state has phenomenal character. Therefore, the notion of a (phenomenally) conscious mental state literally lacking phenomenal character is absurd (Gennaro, 2008; Strawson, 2013): the experience of absence is not equivalent to the absence of experience.

There is, however, a more plausible, non-literal definition of pure consciousness as a conscious state lacking *ordinary* phenomenal content (Gennaro, 2008; Strawson, 2013). The question, then, is what counts as an *ordinary* phenomenal content, and how phenomenally "bare" or "sparse" purely conscious states can get. Presumably, if there are phenomenal properties pertaining to self-consciousness in ordinary experience (i.e., the narrative and somatosensory aspects of self-consciousness previously discussed), then such ordinary phenomenal properties should be missing in purely conscious states, among other ordinary phenomenal properties. Defined in this way, pure consciousness appears to be at least conceivable, and constitutes a plausible candidate for a wholly "selfless" state, lacking self-referential thoughts, bodily ownership, body awareness and self-location. The question is now whether purely conscious states can actually occur, specifically during meditation or after psychedelic intake, and whether they differ from states of alleged "non-dual awareness."

In the Hindu and Buddhist traditions, the meditative practice called *Samadhi* aims at inducing a state of deep absorption (Shankman, 2008). The practice of *Samadhi* includes four stages or *jhanas*, culminating in a "formless" or "objectless" state. It relies on successive shifts of attention, first from the breath to somatosensory pleasure, then to mere positive affect, until all intentional objects have been stripped away and only "one-pointed" awareness remains. In the final stage of *Samadhi* practice (i.e., the last *jhana*), "there is no directing of attention, no representation held in focal attention, no pleasure and no aversion, affective contentment has dropped away, and all that remains is an alert, clear, one-pointed, equanimous awareness." (Yamashiro, 2015, p. 7).

The aim of this practice is frequently described as reaching a state of pure consciousness which involves a complete loss of self-consciousness: "attaining *Samadhi* is to reach the silent state of pure consciousness where there is no phenomenological content and a loss of any sense of individual self or duality" (Wahbeh *et al*., 2018, p. 6)[12]. Miri Albahari has suggested that the state of pure consciousness allegedly reached through *Samadhi* meditation could provide evidence for the existence of what she calls "witness-consciousness," which she defines as the neutral common denominator between all conscious experience (Albahari, 2009). She argues that witness-consciousness has its own intrinsic phenomenal character, which explains why purely conscious states in *Samadhi* are not devoid of phenomenal content, and thus not logically inconsistent. However, this hypothesis seems unduly inflationary: rather than postulating that a special "objectless" phenomenology is ubiquitous in consciousness and is the only thing remaining in purely conscious states, one may seek to describe such states as a form of deep absorption associated with extreme sensory gating which does not have much in common with ordinary experience.

Unfortunately, the neurophysiological evidence regarding *Samadhi* practice is still extremely sparse (Yamashiro, 2015). A single-participant study found decreased activity in Brodmann areas 5 and 7, which may be associated with the representation of the body's orientation in three-dimensional space (Hagerty *et al*., 2013). This reflected the participant's experience of losing body boundaries. Nash and Newberg (2013) also suggest that activity of the posterior parietal lobule is modulated by *Samadhi*, and "might be critical for

[12] As previously noted, it is by definition impossible for a phenomenally conscious mental state to lack any phenomenal content. More realistically, states induced by *Samadhi* practice might lack *ordinary* phenomenal content.

distinguishing between the self and the external world" (Nash and Newberg, 2013, p. 8). Another contemplative tradition which aims at inducing pure consciousness is transcendental meditation (TM), whose goal is the "loss of boundaries of time, space, and body sense that defines the framework for typical waking experience," but neurophysiological data on TM is also very limited (Travis and Pearson, 2000; Wahbeh *et al.*, 2018).

It is unclear to what extent the notions of non-dual awareness and pure consciousness should be distinguished, both in terms of their conceptualization in the relevant literature on contemplative traditions, and in terms of the phenomenology and neurophysiology of the associated states induced by meditation. According to Josipovic, NDA meditation is not content-driven like focused attention and open monitoring, because it seeks awareness of the background of experience rather than any specific bodily or perceptual content (Josipovic, 2014). Moreover, he argues that NDA meditation also differs from "objectless" meditation "in which the mind is emptied of content and held in an empty state through the force of concentration" (Josipovic, 2014, p. 12)[13]. Indeed, Josipovic contends that pure consciousness practice like *Samadhi* aims at actively "eliminating" each pole of the subject/object dichotomy, while NDA meditation involves the recognition of a background non-dual awareness that "precedes conceptualization and intentionality" (Josipovic, 2014, p. 12). Likewise, John Dunne argues that non-dual awareness differs from objectless meditation techniques such as *Samadhi* insofar as it should not involve any cognitive effort (Dunne, 2011). However, these conceptual distinctions are not straightforward, and there is not yet enough data on the phenomenology and neurobiology of alleged states of "pure consciousness" and "non-dual awareness" to determine whether these are valid and distinct constructs.

[13] However, recent data suggests that TM practice does not involve focused attention either and relies on distinct mechanisms; given that TM is often described in terms of pure consciousness, this casts doubt on Josipovic's assumption that "objectless" meditation is a form of focused attention (Travis and Parim, 2017).

As we have suggested, one possible construal of non-dual awareness is in terms of the inhibition of both narrative and multisensory aspects of self-consciousness, leading to a temporary loss of experiential boundary between self and world, or between endogenous and exogenous stimuli. In turn, purely conscious states could be defined as states of extreme absorption involving high sensory gating, whose sparse phenomenal content has little overlap with the rich phenomenology of ordinary wakeful experience. If these tentative definitions are sound, states of pure consciousness should also be states of non-dual awareness, because they should lack ordinary phenomenal content *including* the narrative and multisensory components of self-consciousness. By contrast, non-dual awareness might not entail pure consciousness, because states of total self-loss (lacking narrative and multisensory self-consciousness) need not have very sparse phenomenal content.

This raises the question of whether psychedelic drugs can induce virtually "contentless" states similar to the descriptions of pure consciousness from mystical and contemplative traditions. While most reports of drug-induced ego dissolution involve a rich sensory phenomenology, including vivid hallucinations, this is not always the case. In particular, there is anecdotal evidence that certain compounds such as 5-MeO-DMT may induce states of radical absorption reminiscent of *Samadhi* practice[14]. Indeed, users of 5-MeO-DMT frequently describe an experience of "emptiness," "nothingness" or "void" which is associated with a cessation of thoughts, extreme sensory deprivation and a complete loss of self-consciousness: "my brain was not conveying anything meaningful from what my senses were receiving; I was completely unaware of my body, experiencing profound stillness" (report #99920 from Erowid.org); "I felt that there was nothing to me and there was nothing around me" (#11701); "the reality around me disintegrated into nothing. I fell into a void [that] I can't even describe" (#23487); "I wasn't anything anymore. I had been broken down into nothingness, into oblivion" (#87426); "my thoughts ceased to exist, and my senses shut off completely. I could not hear, see, smell, taste or feel anything" (#37301). This suggests that states of drug-induced ego dissolution may vary not only according to the extent to which narrative and multisensory aspects of self-consciousness are inhibited, but also according to the richness or sparsity of their phenomenology. While some forms of self-loss induced by psychedelics may involve a rich sensory phenomenology, others are more similar to descriptions of "pure consciousness," and may be almost devoid of sensory content.

[14] Some narrative reports about 5-MeO-DMT from Erowid.org explicitly refer to *Samadhi* practice: "Everything I've read about enlightenment and the attainment of *Samadhi* makes perfect sense to me now. It has all become so obvious. During this part of the experience I am not me, I am simply awareness" (#88450), "an immediate complete dissolution of any identity and a merging into the oneness, timeless, pure awareness... similar in some ways with a previous *Samadhi* meditation experience" (#5804).

Toward a multidimensional model of altered self-consciousness

In what precedes, we have suggested that some meditation practices and some psychedelic substances can disrupt self-consciousness in different ways, or more precisely can disrupt different aspects or components of self-consciousness. This analysis stems from the assumption that self-consciousness is not a simple or unidimensional construct, as many other authors have emphasized (Blanke and Metzinger, 2009; Gallagher, 2013; Metzinger, 2014; Zahavi, 2014). We have proposed to organize different components of self-consciousness into two main categories, roughly equivalent to the influential dichotomy between "narrative" and "embodied" self-hood. Unlike some models of the narrative/embodied self-distinction, however, we have suggested that each of these dimensions can be modulated by meditation and drugs in different ways, and to different degrees. The resulting picture can be simplified in the form of a two-dimensional model of "self-loss" or "ego dissolution," which is etiology-independent insofar as both meditation-induced and drug-induced altered states of consciousness could be located within this model, and overlap in some cases (Figure 1A).

This two-dimensional model is greatly simplified, because it suggests that the loss of body ownership, bodily awareness and self-location are all degrees of self-loss that can be ordered along the same dimension. Available evidence does suggest that this is often the case: for example, patients with somatoparaphrenia lack body ownership without lacking bodily awareness and self-location; individuals undergoing bodiless dreams, asomatic out-of-body experience and some psychedelic states (e.g., DMT-induced states) lack both body ownership and bodily awareness, but not necessarily self-location; and finally full-blown drug-induced ego dissolution, particularly after administration of 5- MeO-DMT, appears to involve the loss of all three components. Nonetheless, as we have mentioned, it is unclear whether meditation-induced states can involve a complete loss of bodily awareness (including interoceptive awareness), while it does seem that they can involve a loss of self-location. Thus, this two-dimensional model should be considered at most as a helpful idealization which reduces the dimensionality of the notion of self-consciousness. A more complex and accurate model would probably involve more dimensions (Figure 1B; see Bayne *et al*., 2016 on multidimensional accounts of global states of consciousness in general). In our example, we have represented global states of consciousness within a six-dimensional state space which models various cognitive and multisensory features of self-consciousness as independent dimensions (although systematic correlations are possible). Furthermore, this complex model takes into account another important variable to identify phenomenally distinct forms of self-loss, namely the overall richness or sparsity of phenomenology or the "bandwidth" of conscious contents. This parameter is relevant because many drug-induced states, including some of those reported as instances of drug-induced ego dissolution, have a rich sensory and emotional phenomenology, contrary to meditation-induced instances of self-loss. A more sophisticated model could perhaps take into account additional parameters, such as the sense of agency (see the end of section Spatial self-location above). Meditation-induced states involve intense attentional control at least during certain stages of the practice, unlike drug-induced states, although it is not obvious that this always results in a greater sense of agency in meditation than in psychedelic states. States of "objectless" or "pure consciousness" which lack ordinary phenomenal content, such as those induced by *Samadhi* practice and perhaps by certain psychedelics like 5-MeO-DMT, should be represented in the central region of this model, scoring the lowest in most if not all dimensions. Finally, it should be noted that "access to autobiographical information" is not on par with other dimensions of our tentative model, insofar as it is a functional and dispositional feature rather than phenomenological feature of conscious episodes. Nonetheless, as discussed in section Alterations of self-consciousness induced by meditation and psychedelics, the inability to retrieve semantic autobiographical information may occasionally be associated with a specific phenomenology of retrograde amnesia which differs from the mere cessation of self-related thoughts.

FIGURE 1 - Multidimensional models of self-loss in global states of consciousness. **(A)** A simplified two-dimensional model of self-loss. The X-axis represents the degree to which multisensory aspects of self-consciousness are disrupted, and the Y-axis represents the degree to which narrative aspects of self-consciousness are disrupted. The color gradients represent the gradual disruption of narrative aspects (blue), multisensory aspects (red), or both (yellow) within the two-dimensional state space of altered states of consciousness induced by meditation and psychedelics could theoretically be plotted. This two-dimensional model can be conceived as a conceptual sketch that reduces the dimensionality of the notion of self-consciousness to two orthogonal principal dimensions, somewhat similarly to Principal Component Analysis. The shortcomings of this simplified model are tentatively addressed in the more complex **(B)**. **(B)** A tentative multidimensional model of self-loss. Global states of consciousness are plotted on the radar chart according to their score on six dimensions (using an arbitrary scale), representing the degree to which they involve (1) a sense of body ownership, (2) awareness of bodily sensations, (3) awareness of spatial self-location, (4) rich phenomenology, (5) access to semantic autobiographical information, and (6) self-related thoughts. Regions in the radar chart represent idealized examples of global states of consciousness, including an ordinary state during wakefulness (dotted black line), two examples of meditation-induced states and two examples of drug-induced states. The region in pink is an example of a typical meditative state with increased bodily awareness (via attentional focus on the breath), slightly decreased overall phenomenal richness (via visual-auditory deprivation) and decreased frequency of self-related thoughts. The region in red is an example of a "selfless" state described by experienced meditators, with a cessation of self-related thought, a loss of body ownership, agency and self-location, and significant reductions in bodily awareness and phenomenal richness. The region in light green is an example of a state induced by a moderate dose of psychedelic drugs such as LSD or psilocybin, with increased bodily awareness (modulated by salient and unusual bodily sensations) and increased phenomenal richness (via decreased sensory gating and vivid perceptual abnormalities). The region in dark green is an example of drug-induced ego dissolution with a loss of narrative and multisensory aspects of self-consciousness, but rich sensory content. **(B)** illustrates how even states of "total self-loss" as represented by a single region on **(A)** can differ from a phenomenological perspective between meditation (red line) and psychedelics (dark green line). In addition, it shows that some states of consciousness induced by both meditation practice and psychedelics can also score higher than baseline on certain dimensions of self-consciousness, in particular bodily awareness. Overall, states of "self-loss" are the exception rather than the norm for both modes of induction. Finally, it should be noted that the phenomenology of altered states induced by meditation and psychedelics may considerably change over time, sometimes very quickly; consequently, the idealized states plotted on this figure should be considered as phenomenological "snapshots" at a given time. For example, "Psychedelic state 1" (light green line) could be part of the same drug-induced experience as "Psychedelic state 2" (dark green line), assuming that the phenomenology dynamically shifts toward the peak of the experience (during the transition to drug-induced ego dissolution).

Although we have specifically focused on disruptions of self-consciousness in this paper, it is important to underline that both meditation and psychedelics can not only inhibit various aspects of self-experience, but may also *increase* their salience in other cases. In particular, meditation techniques focusing on the awareness of the breath, as well as psychedelic drugs such as LSD and psilocybin, may temporarily increase awareness of bodily sensations. This apparent paradox is resolved when one considers the many parameters that may modulate the phenomenology of meditation practice and psychedelic states. As we have insisted, there are many different styles of meditation, and states of "self-loss" are usually reported by highly experienced individuals trained in specific traditions. Moreover, the phenomenology of a single meditation session unfolds in distinct phases, with the occasional experience of self-loss being the culmination of this succession of phase transitions (Yamashiro, 2015; see Ataria *et al*., 2015; Dor-Ziderman *et al*., 2016). Similarly, the phenomenology of psychedelic states may be modulated by a number of variables, including: the particular drug used (e.g., the effects of 5-MeO-DMT appear to differ from those of other psychedelics), dosage (high doses being more likely to lead to ego dissolution), context of use (immobility and sensory deprivation may modulate the loss of body awareness and self-location) and finally pharmacodynamics (the effects of a drug evolve across time, with experiences of self-loss occurring at the peak, if at all). In **Figure 1B**, we have represented four examples of global states of consciousness induced by meditation and psychedelics to emphasize these nuances. Only two of these states (represented in red and dark green respectively) may be described as involving experiences of "total self-loss" as depicted on **Figure 1A**, although they do not completely overlap in the multidimensional state space. We have tentatively summarized in **Table 4** below how such states of self-loss might differ between meditation and psychedelics.

The upshot of this discussion is that there is no such thing as "self-loss" or "ego dissolution" in absolute terms. Future research could develop new tools to assess in a more fine-grained way the features of conscious states described as involving a loss of one's sense of self. As an example, neuroimaging studies of psychedelics have often used a single questionnaire item ("I experienced a disintegration of myself or ego") to measure drug-induced ego dissolution and correlate its intensity with neurophysiological observations (Muthukumaraswamy *et al.*, 2013; Carhart-Harris *et al.*, 2014, 2016b; Lebedev *et al.*, 2016; Tagliazucchi *et al.*, 2016). While this strategy has yielded very interesting results, it does not allow for the discrimination between several kinds of disruption of self-consciousness. The recent Ego Dissolution Inventory, which has been psychometrically validated, does not discriminate between the loss of narrative and embodied or multisensory aspects of self-consciousness either (Nour and Carhart-Harris, 2017). Future questionnaires focusing on alterations of self-consciousness could include both items related to disruptions of self-related thoughts and mental time travel, and items related to body ownership, bodily awareness and self-location. A psychometric analysis of subsequent item ratings could test whether these items can be grouped into two orthogonal factors, namely narrative and embodied self-loss.

Table 4 - Summary of overlap and differences between meditation-induced and drug-induced states of "total self-loss"

	Self-loss in psychedelic states	Self-loss in meditation
Body ownership	- - -	- - -
Bodily awareness	- - -	- -
Self-location	- - -	- - -
Phenomenal richness	+ + + (except 5-MeO-DMT)	- -
Self-related thoughts	- -	- - -
Access to semantic autobiographical information	- -	-

It is also important to underline that evidence from subjective reports should be treated with caution. Although the reports discussed in this paper show a remarkable convergence and can be treated as preliminary evidence for the disruption of body ownership, bodily awareness and self-location in meditation and psychedelic states, alternative interpretations are available. First, one could refuse to take these self-reports at face value on the ground that they could be systematically unreliable and confabulatory. This is rather unlikely, however, given the convergence of reports from different groups of subjects in different conditions, as well as the consistency of reports with questionnaire data. Moreover, there is no reason to suspect that either meditators or volunteers participating in studies of psychedelic drugs are particularly prone to confabulation, and their reports are less problematic than those of patients suffering from delusions such as the Cotard syndrome (Billon, 2016). In addition, the microphenomenological interview used to collect some of these reports is designed to minimize the risk of confabulation and theoretical contamination (Petitmengin, 2006; Petitmengin and Lachaux, 2013). Finally, there is some evidence that meditative experience predicts introspective accuracy (Fox *et al.*, 2012; Baird *et al.*, 2014). Nonetheless, it should be noted that the evidence discussed in this article is still tentative insofar as most studies of the effects of meditation and psychedelics rely on a limited sample size.

A second alternative interpretation of the reports discussed in the previous sections would emphasize that the experience of loss is not equivalent to the loss of experience. In other words, the fact that subjects report having a sense of *losing* ownership over their body or awareness of their spatial location does not necessarily entail that body ownership or self-location were part of their overall phenomenology at baseline (i.e., prior to meditating or drug administration). While this idea is not incoherent, we have provided independent reasons to believe that at least bodily awareness and spatial self-location are part of the content of ordinary conscious experience; in other words, there is evidence that we usually experience bodily sensations, and have some awareness of our relative location with respect to our perceived environment. While we acknowledge that the existence of a specific phenomenology of body ownership is more controversial, we have also mentioned some clinical and experimental evidence from somatoparaphrenia, autoscopic phenomena, the rubber hand illusion and full-body illusions suggesting that some feature(s) of the ordinary experience of neurotypical individuals are associated with the experience of one's body as one's own.

In order to address the limitations of self-reports, future research could use implicit and behavioral measurements to circumvent the risk of introspective biases. For example, researchers could investigate the representation of trunk-centered peripersonal space, which has been shown to encode self-location (Blanke *et al.*, 2015; Noel *et al.*, 2015; Serino *et al.*, 2015), both during meditation and after psychedelic intake. A plausible prediction is that the boundaries of the full-body (trunk-centered) peripersonal space are blurred both during some instances of drug-induced ego dissolution and some forms of meditation described as a loss of self-location and body boundaries (see Millière, 2017).

Long-term outcomes of altered self-consciousness

Selflessness as a Trait

Accumulating evidence shows that meditation's state effects linger into daily life, to become long-term, trait alterations (Cahn and Polich, 2006). These trait effects include alterations in resting state function or connectivity, as well as structural changes, compared to control groups (Fox *et al.*, 2014; reviewed in Tang *et al.*, 2015). A full review of all the accumulated evidence is beyond the scope of this paper. Instead, here we focus on trait-effects of alterations in self-consciousness, either from the neurophysiological (underlying mechanisms, specifically regarding the DMN) or first-person perspective.

Several studies have provided evidence that meditation practitioners, compared to controls, exhibit reduced resting state DMN activity and connectivity, either using electrophysiology (Berkovich-Ohana *et al.*, 2012, 2013) or fMRI (Hasenkamp and Barsalou, 2012; Berkovich-Ohana *et al.*, 2016). Specifically, resting state functional connectivity analyses showed that following 8-weeks of mindfulness-training, participants demonstrated significantly increased functional connectivity of the anterior DMN region with the auditory/salience network (Kilpatrick *et al.*, 2011). Similarly, long-term mindfulness practitioners showed compared to controls increased functional connectivity between DMN and visual regions (Berkovich-Ohana *et al.*, 2016). In other studies, proficient mindfulness meditators showed increased functional connectivity between the DMN and fronto-parietal control network compared to novices (Brewer *et al.*, 2011; Hasenkamp *et al.*, 2012; Taylor *et al.*, 2013), although there is some evidence of increased anti-correlation between the DMN and a task-positive network during focused attention meditation compared to the resting state (Josipovic *et al.*, 2012), or the DMN and visual regions following MBSR (Kilpatrick *et al.*, 2011). While fMRI studies largely show that mindfulness meditation practice is associated with reduced DMN activity, the related structural effects in the DMN are less clear (recently reviewed by Fox *et al.*, 2014). Specifically, several neuroanatomical studies reported changes in PCC gray matter thickness: while a few studies indicate reduction in meditators relative to controls (Kang *et al.*, 2013), another study failed to find group differences (Grant *et al.*, 2013), and yet another reported gray matter increases following a short 8-weeks mindfulness meditation intervention (Hölzel *et al.*, 2011). Initial evidence suggests that such changes in DMN functioning are indeed related to a reduced tendency to engage in self-referential processing. One earlier study (Farb *et al.*, 2007) showed that after an 8-week mindfulness intervention, participants were able to disengage from a "narrative self-focus" in the trait judgment task (typically employed to investigate self-referential processes, cf. Northoff *et al.*, 2006), as evidenced by more pronounced reductions in the DMN compared to the control group. Similarly, another study found reduced bias in neural responses to the self vs. an other's face for long-term meditators compared to controls (Trautwein *et al.*, 2016).

Less is known about whether meditation practice affects multisensory aspects of self-consciousness in a trait-like manner. Studies investigating neural and phenomenological state effects of meditation suggest that long-term meditators are capable of flexibly modulating and reducing bodily self-awareness (Ataria *et al.*, 2015; Dor-Ziderman *et al.*, 2016). However, controlled studies have not yet systematically assessed whether this is an outcome of long-term practice (some effects also seem to occur in novice practitioners, cf. Dambrun, 2016) and to which degree such flexibility affects daily life functioning.

There is no evidence that the experience of drug-induced ego dissolution may have long-term effects on narrative and multisensory aspects of self-consciousness, such as a reduction of self-related thoughts. This question may be answered by future longitudinal studies.

Relation to Therapeutic Outcomes, Well-Being and Prosociality

While the long-term consequences of ego dissolution on self-consciousness are uncertain, there is preliminary evidence that drug-induced alterations of self-consciousness may mediate therapeutic outcomes. The current model of psychedelic-assisted therapy originated in the 50's and 60's (Pahnke *et al.*, 1971; Dyck, 2006). In this model, subjects receive a high dose of a psychedelic drug in a supportive environment, with the aim of experiencing a mystical-type or "peak" experience (Maslow, 1959; Stace, 1960). This experience is conceived as a "unitive" state involving the loss of self-world boundaries, as described in sections Alterations of self-consciousness induced by meditation and psychedelics and Pure consciousness, non-dual awareness and total selflessness. The therapeutic model suggests that this experience mediates long-term outcomes (Pahnke *et al.*, 1971; Grof *et al.*, 2008; Maji&cacute; *et al.*, 2015; Richards, 2015). In recent years, many controlled studies have shown that that the magnitude of the mystical-type experience predicts positive psychological outcomes for depression, addiction, palliative care, and general well-being (O'Reilly and Funk, 1964; Klavetter and Mogar, 1967; Pahnke *et al.*, 1971; Kurland and Grof, 1972; Richards *et al.*, 1977; Griffiths *et al.*, 2006, 2016; MacLean *et al.*, 2011; Garcia-Romeu *et al.*, 2014; Bogenschutz *et al.*, 2015; Ross *et al.*, 2016; Johnson *et al.*, 2017; Roseman *et al.*, 2018). Furthermore, a recent analysis of the psychedelic experience in uncontrolled environments suggests that mystical-type experiences predict changes in well-being (Carhart-Harris *et al.*, 2018). It is also suggested that mystical-type experiences are linked to the positive emotional outcomes of meditation (Russ and Elliott, 2017).

Two variables appear to predict the occurrence of mystical-type experience in both meditation and psychedelics: trait absorption and surrender state. Absorption (Tellegen and Atkinson, 1974) is a trait characterized by the disposition to have episodes of "total" attention to one's representational resources. Subjects with higher absorption tend to have stronger mystical-type experiences both under psychedelics (Studerus *et al.*, 2012) and in meditation (Russ and Elliott, 2017). The second variable is the pre-experience state characterized by the disposition to "let-go" or "surrender" to whatever experience comes, sometimes called "surrender state" (Richards, 2015). This state is not only related to the subject's personality but also to interactions with the environment (e.g., trust toward the therapist). Higher ratings of willingness to surrender are associated with stronger mystical-type experience in both psychedelic experiences (Carhart-Harris *et al.*, 2018) and meditation (Russ and Elliott, 2017).

Do experiences of "self-loss" induced by meditation or psychedelics have a relevance for therapeutic outcomes or general well-being? There is preliminary evidence that the therapeutic effects of psychedelics for treatment-resistant depression is mediated by meaningful "breakthrough" experiences, which may include ego dissolution (Roseman *et al.*, 2018). By contrast, long-term effects of contemplative practices on well-being do not appear to be necessarily mediated by intense experiences, but rather by training of different cognitive mechanisms, such as attentional control mediating meta-awareness of mind-wandering. Interestingly, one suggested mechanism is a (gradual) shift in the perspective on the self-described as "detachment from identification with a static sense of self " (Hölzel *et al.*, 2011). In the Buddhist tradition, this process is thought to be a crucial factor for the attainment of stable well-being (Olendzki, 2006; Shiah, 2016). Some psychometric research supports this link (Dambrun, 2017). Moreover, a related construct called "decentering" has been found to mediate treatment effects of mindfulness based interventions (reviewed in Bernstein *et al.*, 2015). Anecdotal reports and traditional sources do also claim that peak meditative experiences involving a loss of the sense of self can have lasting effects on well-being (Austin, 2009); however, perhaps due to the difficulty to induce such experiences in the lab, they have not been systematically investigated. In a first qualitative survey on experiences associated with long-term meditative practice, changes in the sense of self, including narrative and bodily levels were frequently reported (more than 75%) (Lindahl *et al.*, 2017). Of note, the affective response to these experiences was not always positive, but ranged "from neutral curiosity, to bliss and joy, to fear and terror" (p. 20). Interestingly, ayahuasca administration was also found to produce after 24 h a significant reduction in judgmental processing of experiences measured by the Five Facets Mindfulness Questionnaire (FFMQ), as well as a significant increase in decentering ability measured by the Experiences Questionnaire (EQ) (Soler *et al.*, 2016). Thus, it is possible that the medium- to long-term effects of meditation and psychedelic experiences involve a reduced tendency to be personally and emotionally engaged in one's thoughts and feelings, such that "the contents of consciousness are less filtered through considerations of self-relevance than is usual" (Letheby and Gerrans, 2017, p. 7).

A further question worth investigating in future research regards the specific kind of "self-loss," if any, which may mediate long-term therapeutic outcome and increased well-being. For example, are such effects more likely to be mediated by the loss of narrative or multisensory aspects of self-consciousness? Given the potential link between mind-wandering and unhappiness (Killingsworth and Gilbert, 2010), it is intriguing to speculate that increased control of spontaneous thoughts might mediate increased well-being in experienced meditators, which would indicate that the disruption of narrative aspects of self-consciousness may have a positive effect, to some extent. At this stage, however, this speculative hypothesis remains unsubstantiated by significant evidence.

Besides individual well-being, one potential outcome of meditative practice is an increase in empathy and compassion, which are regarded as antecedents of prosocial behavior. There is indeed evidence that meditation fosters these aspects of prosociality (Condon *et al*., 2013; Ashar *et al*., 2016; see Kreplin *et al*., 2018 for a recent meta-analysis; Leiberg *et al*., 2011; Weng *et al*., 2013). Importantly, it has been hypothesized that these effects rely on a change in the sense of self. For example, Dambrun and Ricard (2011) suggested that meditation can support a shift from self-centered to selfless functioning, characterized by "a weak distinction between self and others, and self and the environment as a whole," which in turn "is closely related to characteristics such as altruism, kindness, respect, empathy, compassion and the search for harmony" (Dambrun and Ricard, 2011, p. 140). Providing evidence for one part of this relationship, recent studies demonstrated that manipulation of bodily levels of self-awareness can affect empathy and social cognition (Maister *et al*., 2013, 2015). However, the link to meditation is still largely hypothetical, although one study found that reduced self-related processing in long-term meditators was correlated with increased trait levels of self-reported compassion (Trautwein *et al*., 2016). Intriguingly, the administration of a high dose of psilocybin 1 or 2 months after a program of meditation practice was found to occasion enduring trait-level increases in prosocial behavior (Griffiths *et al*., 2018). This finding raises the question of whether psychedelic intake may potentiate in certain cases the putative long-term effects of meditation on prosociality. In summary, it is possible that there is a link between "selflessness" as a conscious episode lacking self-consciousness and trait increase in prosocial behavior, but these two constructs should not be conflated. Future research could determine whether such an association exists for meditation training and perhaps psychedelic use, and get clearer on the mechanisms involved.

General conclusion

There is converging evidence that high doses of psychedelic drugs and certain forms of meditation practice for highly experienced practitioners can produce strong, short-term, and reversible disruptions of self-consciousness. However, drug-induced and meditation-induced experiences of "self-loss" are not uniform, and can be decomposed in terms of alterations of various aspects or dimensions of self-consciousness. These include "narrative" aspects, such as the inhibition of self-related thoughts and self-related mental time travel, and the loss of access to autobiographical information, as well as bodily and multisensory aspects, such as the loss of body ownership, bodily awareness and self-location. Questionnaire data, subjective reports and neurophysiological results suggest that some of these aspects might be independently modulated in the global states of consciousness that can be induced by meditation and psychedelic drugs. Thus, the notion of self-consciousness can be construed as a multidimensional construct, and consequently "self-loss" or "ego dissolution" should not be conceived as a simple graded phenomenon ordered along a single dimension.

Moreover, even forms of putative "total" self-loss involving the radical disruption of both narrative and multisensory aspects of self-consciousness are best thought of as a family of states which can differ from a phenomenological perspective with respect to variables that are not directly related to self-consciousness. Indeed, strong forms of drug-induced ego dissolution may involve a very vivid and rich sensory phenomenology, perhaps as a result of decreased sensory gating, while available evidence on some "selfless" states induced by meditation suggests that their phenomenal content is very sparse (e.g., in states of so-called "pure consciousness" achieved in *Samadhi* practice).

One potential limitation of this analysis is that empirical data remains too sparse to reliably determine the phenomenological and neurophysiological specificity of the global states of consciousness under consideration. For example, it remains difficult to assess in what respect conscious states induced by *Samadhi* practice really differ from states induced by other meditation practices or psychedelic drugs. Few controlled studies have investigated the experience of self-loss in meditation or drug-induced states, and those which have done so have limited sample sizes. Another potential issue is the interpretation of self-reports. It is notoriously difficult to gather reliable evidence about subjective experience, and this is all the more problematic with altered states of consciousness often deemed ineffable.

Future research on this topic could focus on developing more fine-grained psychometric tools to validate and measure various dimensions of self-consciousness, and their respective disruptions in altered states of consciousness. Furthermore, researchers could seek to correlate reports gathered from questionnaires not only with neuroimaging data, but also with independent implicit measurements. As an example, the disruption of spatial self-location might be associated with a dissolution of the boundaries of the trunk-centered peripersonal space, which can be measured using an established psychophysical paradigm (Noel *et al.*, 2015). Finally, future research could investigate the possible relationship between temporary disruptions of self-consciousness induced by meditation and psychedelics, and long-term changes in cognitive processing, personality traits and prosocial behavior. While it is important to avoid conflating states of self-loss with "selflessness" as a trait or moral construct, it is possible that correlations might exist between these distinct notions, although perhaps only for a subset of highly experienced meditators or drug-users. More research is needed to provide answers to these outstanding questions.

Author contributions

All authors listed have made a direct contribution to the work. RM has written the first draft of the manuscript, with the exception of the final section Long-term outcomes of altered self-consciousness. RC-H, LR, F-MT and AB-O have written the latter, and have completed the section The neuroscience of meditation and psychedelics: an overview. All authors listed have contributed to subsequent revisions of the manuscript.

Funding

RM was funded by the Ertegun Scholarship Programme. RC-H was funded by the Alex Mosley Charitable Trust. LR was funded by Imperial College London, President's PhD Scholarship and by Albert Hobohm. F-MT was funded by a DFG individual fellowship (GZ: TR 1587/1-1). AB-O was funded by a grant from the Bial Foundation (228/14).

Acknowledgements

The authors would like to thank Martin Davies, Link Swanson and Christopher Timmermann for their helpful comments on previous versions of this article.

Conflict of Interest Statement: The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Abstract - The authors interviewed 53 cluster headache patients who had used psilocybin or lysergic acid diethylamide (LSD) to treat their condition. Twenty-two of 26 psilocybin users reported that psilocybin aborted attacks; 25 of 48 psilocybin users and 7 of 8 LSD users reported cluster period termination; 18 of 19 psilocybin users and 4 of 5 LSD users reported remission period extension. Research on the effects of psilocybin and LSD on cluster headache may be warranted.

Cluster headache, often considered the most painful of all types of headache,[1] affects predominantly men (0.4% vs 0.08% of women) and typically begins after age 20 years. The disorder is categorized as either *episodic*, occurring for 1-week to 1-year periods, interspersed with pain-free remission periods, or *chronic*, in which the headaches occur constantly for more than a year with no remission longer than 1 month.[2] Ten percent of episodic cluster headaches ultimately evolve into the chronic form, and these are termed *secondary chronic*. In standard descriptions of cluster headache, an *attack* refers to the actual paroxysm of pain, a *cluster period* refers to a period of time when attacks occur regularly, and a *remission* period refers to a prolonged attack-free interval. [3] Oxygen and sumatriptan are the mainstays of acute abortive treatment, whereas verapamil, lithium, corticosteroids, and other neuromodulators can suppress attacks during cluster periods. No medications are known to terminate cluster periods or extend remission periods. The effects of the ergot alkaloid derivative lysergic acid diethylamide (LSD) and the related indolalkylamine psilocybin on cluster headache have not previously been described and may include such properties.

Case series. We were contacted by a 34-year-old man, diagnosed with episodic cluster headache at age 16 years, who reported a complete remission of his cluster periods when he repeatedly used LSD on a recreational basis between ages 22 and 24 years. Cluster periods resumed once he stopped. Based on this experience, he attempted to treat his cluster headache by ingesting psilocybin-containing mushrooms every 3 months and again achieved lasting remission. On three occasions when he missed his scheduled dose, a cluster period reoccurred.

Intrigued by this history, we located-through cluster headache support groups and an Internet-based survey-several hundred people with cluster headache who reported use of psilocybin-containing mushrooms or LSD specifically to treat their disorder, and we administered a standardized questionnaire (available from the authors). The consent form and study were approved by the McLean Hospital institutional review board. We restricted our analysis to the 53 individuals who 1) agreed to be contacted for evaluation by telephone or e-mail and 2) met International Classification of Headache Disorders-2 criteria for cluster headache and allowed us to obtain copies of medical records documenting a diagnosis of cluster headache by an MD or DO. If the medical records did not support the diagnosis, the subject was excluded from further analysis. The final sample included subjects from across the United States as well as Great Britain, The Netherlands, and South Africa. We found no significant differences between men and women on demographic indices or headache features (table 1). Notably, 31 (58%) of the 53 individuals reported that they had never used psilocybin or LSD except to treat their cluster headache, and a further 13 (25%) had used these drugs for recreational purposes only in the remote past during adolescence.

Results are summarized in table 2 and listed in complete form in table E-1 (on the Neurology Web site at www.neurology.org). Of the 32 subjects with episodic cluster headache, 19 had used sublingual psilocybin during cluster attacks; 17 found psilocybin to be effective in aborting attacks (defined as ending the attack within 20 minutes). Only one subject had used sublingual LSD for an acute attack, reporting it to be effective. Twenty-nine subjects had used psilocybin prophylactically during a cluster period; 15 (52%) reported that it was effective (defined as causing total cessation of attacks), and a further 12 (41%) reported partial efficacy (defined as attacks decreasing in intensity or frequency but not ceasing). Five of six LSD users reported cluster period termination. Twenty subjects ingested psilocybin during a remission period; 19 reported an extension of their remission period, in that their next expected cluster period was delayed or prevented entirely. Four of five subjects reported similar remission extension with LSD.

Of the 21 subjects with chronic cluster headache, 5 of 7 reported that psilocybin aborted a cluster attack; 10 of 20 reported that psilocybin induced a complete termination of cluster attacks; and a further 8 reported partial efficacy. Of two chronic cluster headache patients who ingested LSD, both at subhallucinogenic doses, one reported no attacks for 10 days, and the other reported none for 2 months. Interestingly, 22 (42%) of the 53 subjects reported partial or complete efficacy (as defined above) from subhallucinogenic doses of psilocybin or LSD.

Discussion

Our results are interesting for three reasons. First, no other medication, to our knowledge, has been reported to terminate a cluster period. Second, unlike other ergot-based medications, which must be taken daily, a single dose of LSD was described as sufficient to induce remission of a cluster period, and psilocybin rarely required more than three doses. Third, given the apparent efficacy of subhallucinogenic doses, these drugs might benefit cluster headache by a mechanism unrelated to their psychoactive effects.

Several limitations of this study should be considered. First, it is subject to recall bias, because it relies primarily on participants' retrospective reports. However, 6 participants (11%) provided detailed headache diaries that corroborated their recall. In addition, 3 (6%) of the 53 participants tried psilocybin for the first time subsequent to consenting to participate in the study but before being questioned; 2 reported complete efficacy and 1 reported partial efficacy - a prospective response rate consistent with our retrospective findings.

A second consideration is the possibility of selection bias, in that individuals with a good outcome may have been more likely to participate. Recruitment over the Internet also selects for younger, more educated, and more motivated subjects,[4] likely leading to increased reported efficacy.

Table 1. Cluster headache characteristics by sex and subtype.

Headache type	n	Age, y	Headache features			
			Attack duration, min	Attacks/day at peak	Cluster period duration, wk	Remission period duration, wk
Episodic						
Men	26	45 (8)	97 (66)	5.5 (3.7)	13 (10)	11 (10)
Women	6	45 (11)	66 (34)	6.2 (3.0)	15 (10)	9 (5)
Total	32	45 (8)	91 (60)	5.6 (3.5)	13 (10)	11 (9)
1° Chronic						
Men	6	48 (8)	79 (57)	9.8 (7.4)	NA	NA
Women	1	38 (NA)	90 (NA)	8.0 (NA)		
Total	7	47 (8)	81 (53)	9.6 (6.8)		
2° Chronic						
Men	10	45 (6)	105 (70)	6.9 (3.0)	NA	NA
Women	4	46 (10)	139 (64)	7.5 (1.0)		
Total	14	45 (7)	115 (68)	7.1 (2.5)		

Data are presented as mean (SD).
1° = primary; 2° = secondary; NA = not applicable.

Table 2. Reported efficacy of principal reported treatments for cluster attacks, cluster periods, and remission extension.

Medication	Total, n	Effective, n (%)	Partially effective, n (%)	Ineffective, n (%)
Acute treatment				
Oxygen	47	24 (52)	19 (40)	4 (9)
Triptans	45	33 (73)	8 (18)	4 (9)
Psilocybin	26	22 (85)	0 (0)	4 (15)
LSD	2	1 (50)	0 (0)	1 (50)
Prophylactic				
Propanolol	22	0 (0)	2 (9)	20 (91)
Lithium	20	1 (5)	8 (40)	11 (55)
Amitriptyline	25	0 (0)	4 (16)	21 (84)
Verapamil	38	2 (5)	22 (58)	14 (37)
Prednisone	36	15 (45)	5 (14)	15 (42)
Psilocybin	48	25 (52)	18 (37)	3 (6)
LSD	8	7 (88)	0 (0)	1 (12)
Remission extension				
Psilocybin	22 (31)	20 (91)	NA	2 (9)
LSD	5 (7)	4 (80)	NA	1 (20)

Nine additional individuals had taken psilocybin and two additional had taken lysergic acid diethylamide (LSD) purposefully for remission extension but were not yet due for another cluster period at the time of our evaluation; hence, for them, efficacy could not be scored.

Third, participants were not blind to their treatment, raising the possibility of a placebo response. However, cluster headache is known to respond poorly to placebo; controlled trials have shown a placebo response of 0% to prophylactic medications such as verapamil, [5] capsaicin,[6] and melatonin,[7] and less than 20% to abortive medications such as sumatriptan.[8] Therefore, it seems unlikely that we would have found more than 50 cases of apparent response to psilocybin or LSD through placebo effects alone.

Our observations must be regarded as preliminary, in that they are unblinded, uncontrolled, and subject to additional limitations as described above. Therefore, our findings almost certainly overestimate the response of cluster headache to psilocybin and LSD and should not be misconstrued as an endorsement of the use of illegal substances for the self-treatment of cluster headache. However, given the high reported efficacy for this notoriously refractory condition, it is difficult to dismiss this series of cases as entirely artifactual. Further research is warranted.

Acknowledgment

The authors thank Nancy K. Mello, PhD, and Kimberley Lindsey, PhD, for their comments on an earlier version of this manuscript, and Robert Wold, Earth and Fire Erowid, for assistance with data collection.

Background: Anecdotal reports suggest that psychedelic agents may relieve symptoms of obsessive-compulsive disorder (OCD). This modified double-blind study investigated the safety, tolerability, and clinical effects of psilocybin, a potent 5-HT_{1A} and $5\text{-HT}_{2A/2C}$ agonist, in patients with OCD.

Method: Nine subjects with DSM-IV-defined OCD and no other current major psychiatric disorder participated in up to 4 single-dose exposures to psilocybin in doses ranging from subhallucinogenic to frankly hallucinogenic. Low (100 µg/kg), medium (200 µg/kg), and high (300 µg/kg) doses were assigned in that order, and a very low dose (25 µg/kg) was inserted randomly and in double-blind fashion at any time after the first dose. Testing days were separated by at least 1 week. Each session was conducted over an 8-hour period in a controlled environment in an outpatient clinic; subjects were then transferred to a psychiatric inpatient unit for overnight observation. The Yale-Brown Obsessive Compulsive Scale (YBOCS) and a visual analog scale measuring overall obsessive-compulsive symptom severity were administered at 0, 4, 8, and 24 hours post-ingestion. The Hallucinogen Rating Scale was administered at 8 hours, and vital signs were recorded at 0, 1, 4, 8, and 24 hours after ingestion. The study was conducted from November 2001 to November 2004.

Results: Nine subjects were administered a total of 29 psilocybin doses. One subject experienced transient hypertension without relation to anxiety or somatic symptoms, but no other significant adverse effects were observed. Marked decreases in OCD symptoms of variable degrees were observed in all subjects during 1 or more of the testing sessions (23%-100% decrease in YBOCS score). Repeated-measures analysis of variance for all YBOCS values revealed a significant main effect of time on Wilks lambda (F = 9.86, df = 3,3; p = .046), but no significant effect of dose (F = 2.25, df = 3,3; p = .261) or interaction of time and dose (F = 0.923, df = 9,45; p = .515). Improvement generally lasted past the 24-hour timepoint.

Conclusions: In a controlled clinical environment, psilocybin was safely used in subjects with OCD and was associated with acute reductions in core OCD symptoms in several subjects.

(J Clin Psychiatry 2006;67:1735-1740)

Preface

Obsessive-compulsive disorder (OCD) is a chronic and debilitating condition with a lifetime prevalence of 2% to 3%, which makes it the fourth most common psychiatric diagnosis[1,2] and one with a very high disease burden.[3] Furthermore, OCD is commonly complicated by the presence of comorbid delusions, suicidality, panic, substance abuse, depression, and interpersonal difficulties. Many patients with OCD delay or altogether avoid pursuing care, and of those who seek help, many remain unrecognized and untreated.

It is now well established that serotonin (5-HT) reuptake inhibitors (SRIs), such as the selective serotonin reuptake inhibitors (SSRIs) and clomipramine, are among the most effective pharmacologic treatments for OCD, although these treatments generally reduce symptoms by only 30% to 50%.[4,5] Some SRI-treated patients who receive the 5-HT_2 antagonist metergoline experience a resurgence of OCD symptoms.[6] Supporting the central role of 5-HT in the efficacy of SRIs, drugs such as desipramine and bupropion, which may act primarily by blocking reuptake of norepinephrine and/or dopamine, are not effective treatments for OCD.[7,8]

In spite of the greater efficacy of potent SRIs compared with other agents in the treatment of OCD, they are still suboptimal. The length of time required for improvement of patients undergoing treatment with SRIs is quite extensive, the rates of remission are minimal, and many patients considered responders have residual symptoms that continue to cause dysfunction and may increase vulnerability to complications and exacerbations.[9] In addition to SRIs, other effective treatments include cognitive behavioral psychotherapy (CBT), combination of SRIs and CBT, and the use of polypharmacy.[5,9] It is estimated that as many as 40% to 60% of those who are adequately treated will fail to respond to standard therapies.[9] For these reasons, identifying new options for treatments has become a high priority.

There are several reported cases concerning the beneficial effects of hallucinogenic drugs (psilocybin and lysergic acid diethylamide [LSD]) in patients with OCD and related disorders.[10-14] For example, a 34-year-old man had suffered from OCD symptoms (checking and counting compulsions, performing actions a specific number of times, and a variety of other rituals) since age 14. However, he began using freeze-dried psilocybe mushrooms recreationally at age 18 and observed consistently that during the psilocybe mushroom intoxication, he was free of obsessions or compulsions. Repeated use induced tolerance to the psychedelic effects, but the subject continued to experience relief of his OCD symptoms despite the lack of a "high." Chronic use of this hallucinogen led to a symptomatic remission, which lasted for several months after discontinuing use.[15]

Psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine), an indolealkylamine, is the main active compound of many species of the genus Psilocybe, commonly known as "magic mushrooms." Psilocybin binds potently as an agonist to the 5-HT$_{1A}$, 5-HT$_{2A}$, and 5-HT$_{2C}$ receptors. [16,17] Behavioral pharmacology and electrophysiologic research show that agonist activity at 5-HT$_2$ receptors strongly correlates with a stimulus effect in animals and a hallucinogenic effect in humans.[18,19] Oral doses ranging from 8 to 20 mg p.o. or 100 to 315 µg/kg are considered safe and able to induce a quantifiable psychedelic experience that lasts, depending on the dose, from 3 to 8 hours.[20,21] Given a large first-pass metabolism in which psilocybin is converted primarily to psilocin, the latter may actually be responsible for the psychotropic effects observed after psilocybin administration.

Given the large body of clinical data suggesting that pharmacologic potency in increasing synaptic 5-HT may underlie the therapeutic effects of some drugs in the treatment of OCD and the anecdotal reports of acute reduction in OCD symptoms with hallucinogens, we hypothesized that agonist activity at 5-HT$_{1A}$, 5-HT$_{2A}$, and/or 5-HT$_{2C}$ receptors might underlie the efficacy of drug treatments for OCD. The present study sought to evaluate the safety, tolerability, and potential therapeutic effect of psilocybin administration in OCD patients who had failed to respond to at least 1 adequate treatment trial with SRI agents. Additionally, we sought to explore the relationship between the intensity of psychedelic experience and the severity of obsessions and compulsions during testing.

Method

Safety and Ethical Considerations

This project was approved by the University of Arizona Human Subjects Committee and the U.S. Food and Drug Administration (FDA). All participants signed informed consent statements, which included a detailed discussion of potential somatic and mental effects of psilocybin. The subject selection and study design were the result of extensive discussions with members of the Human Subjects Committee at the University of Arizona and representatives of the FDA, who had a number of comments geared toward improving the safety of research subjects. The study was conducted from November 2001 to November 2004.

Subjects

Nine subjects (7 male, 2 female) who met criteria for current OCD based on the Structured Clinical Interview[22] for the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV)[23] were recruited through word-of-mouth, Internet postings, and local advertisement. Their ages ranged from 26 to 62 years (mean ± SD = 40.9 ± 13.2 years); 3 of the subjects were employed, 1 was a housewife, and 5 were unable to work because of their OCD symptomatology. Six of 9 participants lived alone, 2 were living with a significant other, and 1 was married.

Subjects were required to have at least 1 "treatment failure," defined as lack of significant improvement after an adequate treatment course with an SRI for at least 12 weeks (based on dose range recommendations published in the Expert Consensus Guidelines for OCD[5]). Subjects had a mean ± SD of 3.4 ± 1.9 treatment failures. Subjects were required to be symptomatic at the time of enrollment and had a baseline Yale-Brown Obsessive Compulsive Scale (YBOCS)[24] score ranging from 18 to 36 (mean ± SD = 24.1 ± 5.9) on the first test day. None of the subjects met criteria for current major psychiatric disorders other than OCD, including current substance abuse/ dependence, and none of the subjects had a personal or family history of psychosis. Due to safety concerns over potential adverse reaction to psychedelic drugs, subjects were required to have tolerated well at least 1 prior exposure to indole-based psychedelics. Two of the subjects (1 and 4) reported a history of clinical benefit with use of psychedelics.

Subjects were free of general medical or neurologic conditions based on the clinical history and review of systems; physical examination; electrocardiogram; routine laboratory blood, urine, and pregnancy screenings; and urine testing for drugs of abuse. Subjects were required to abstain from use of antidepressants for at least 2 weeks (6 weeks for fluoxetine) and any pharmaceutical or nutritional supplement for at least 1 week before testing. Additionally, subjects were free of any other prescription or over-the-counter medication or drug of abuse.

Procedure

Testing was performed in the Department of Psychiatry at the University of Arizona Health Sciences Center. Psilocybin sessions were conducted in the outpatient offices of the Psychopharmacology Research Program. As a cautionary measure, subjects were then transferred to the psychiatric inpatient unit of the same hospital for overnight observation and were discharged the next morning. When a bed was not available in the psychiatric unit, subjects were admitted to the medical-surgical units under the care of the psychiatric service and remained under constant supervision by a staff member. Subjects had an opportunity to develop rapport with the study team during screening. All subjects met with the principal investigator (F.A.M.) and whenever possible with the sitters the day before testing. During the initial visit, further rapport was established, the procedure was again discussed, and the testing room and the psychiatric inpatient unit were shown to the subjects.

Subjects reported for testing at 8:00 a.m., after having had a light snack. Testing for drugs of abuse and pregnancy (when applicable) was conducted prior to each session. Subjects were escorted to the testing room, where they remained for the next 8 hours. Subjects were allowed to use a nearby restroom, but no other outings were allowed. A light snack was again made available for subjects at about 1:00 p.m. Study drug was ingested at about 8:30 a.m. Subjects received up to 4 different doses, 1 dose per test session, in a modified dose escalation blinded protocol. Doses were 25 (very low dose [VLD]), 100 (low dose [LD]), 200 (medium dose [MD]), and 300 (high dose [HD]) µg/kg of body weight. LD, MD, and HD were assigned in that order, and VLD was inserted randomly and in double-blind fashion at any time after the first dose (LD). Testing days were separated by at least 1 week. Subjects were asked to wear eyeshades, listen to a standardized set of music, and minimize interactions during the sessions. Trained sitters were present at all times and included at least 1 of the investigators; whenever possible, a male and a female sitter were present simultaneously. Toward the end of the 8-hour test, subjects were allowed to modify the music selection, have more conversation, discontinue use of the eyeshades, and gradually debrief with the principal investigator regarding aspects of their experience.

Measurements

The YBOCS and a visual analog scale (VAS) for overall obsessive-compulsive symptom severity were administered immediately before psilocybin ingestion (baseline) and at 4, 8, and 24 hours postingestion. The Hallucinogen Rating Scale (HRS)[25] was administered at 8 hours post ingestion. The HRS is a non-theoretically constructed scale, and its item selection is based on reported observations from experienced hallucinogen users who could experience a full range of effects. It measures 6 aspects of the hallucinogenic experience, including the following subscales: somaesthesia, affect, volition, cognition, perception, and intensity. Volition and intensity subscales are compounded by a small number of items and lack the established validity of the other mentioned subscales. Vital signs were monitored at baseline and 1, 4, 8, and 24 hours after psilocybin ingestion.

Data Analysis

Change in YBOCS and VAS scores was assessed by multivariate analysis of variance (ANOVA) in a repeated-measures design. This allowed for an assessment of the main effect of time, dose, and time-by-dose interaction. ANOVA within-subjects linear contrast was utilized to test for dose-response relationship in the HRS intensity subscale. Pearson correlation was used to assess the relationship between HRS intensity score and change in YBOCS score.

Results were considered significant when $p \leq .05$. Trends are also reported when $p \leq .1$. All tests were 2-tailed. Data analysis and graphic presentation utilized SPSS[26] and SYSTAT[27] software programs.

Results

Safety and Tolerability

Subjects generally tolerated the procedure well. One subject experienced transient hypertension (132/90, 135/90, 142/105, 142/95, and 116/78 mm Hg at 0, 1, 4, 8, and 24 hours, respectively, after ingestion of a medium dose of psilocybin), which was not associated with psychic anxiety or somatic symptoms. Two subjects declined further participation after the first testing session due to discomfort with hospitalization. No other adverse reactions were observed. All 9 subjects received LD, 7 of them also received VLD and MD, and 6 of them received all 4 doses.

Effect on OCD Symptoms

Repeated-measures ANOVA for all YBOCS values revealed a significant main effect of time on Wilks lambda (F = 9.86, df = 3,3; p = .046), but no significant effect of dose (F = 2.25, df = 3,3; p = .261) or interaction of time and dose (F = 0.923, df = 9,45; p = .515). Marked decreases in OCD symptoms of variable degree were observed in all subjects during 1 or more sessions (23% - 100% reduction in YBOCS score). Contrast comparison of baseline versus postingestion YBOCS scores for all doses combined was also statistically significant (F = 9.37, df = 1,5; p = .028); see Figures 1 and 2.

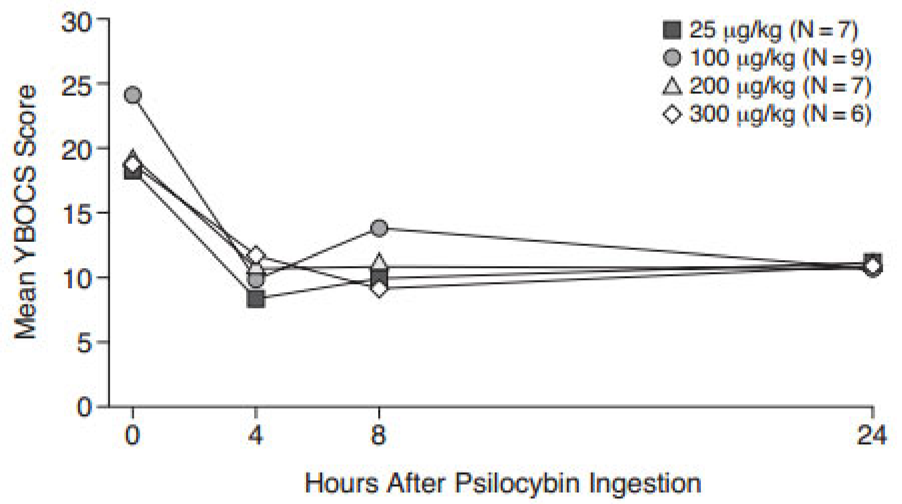

Figure 1. Effects of Psilocybin on Obsessive-Compulsive Symptom Severity[a]

[a] Mean YBOCS scores immediately prior to ingesting psilocybin (T-0) and 24 hours after ingesting psilocybin (T-24) for each dose were as follows: 25 µg/kg, T-0 = 18.29, T-24 = 11.14; 100 µg/kg, T-0 = 24.11, T-24 = 10.67; 200 µg/kg, T-0 = 19.57, T-24 = 11.00; 300 µg/kg, T-0 = 18.83, T-24 = 11.33.

Abbreviation: YBOCS = Yale-Brown Obsessive Compulsive Scale.

Repeated-measures ANOVA for effects of individual doses on YBOCS scores found a significant effect of time for LD (p = .004) and MD (p = .006), but not for VLD (p = .128) or HD (p = .406). Changes in obsessions and compulsions were comparable. ANOVA of baseline to 24 hours YBOCS score also showed a significant effect of time (F = 7.89, df = 1,5; p = .038), but no effect of dose or time-by-dose interaction.

VAS scores for all doses combined showed no significant effect of time (F = 3.05, df = 3,3; p = .192) or dose (F = 2.7, df = 3,3; p = .218). Repeated-measures ANOVA for effect of individual doses on VAS scores found a significant effect of time for LD (p = .010), but not for VLD (p = .307), MD (p = .182), or HD (p = .25). Contrast comparison of baseline versus postingestion VAS scores for all doses combined was also statistically significant (F = 11.41, df = 1,5; p = .020). ANOVA of baseline to 24 hours revealed a significant main effect of time (F = 5.38, df = 1,5; p = .068), a nonsignificant effect of dose (F = 1.83, df = 3,3; p = .316), and a significant interaction of time and dose (F = 183.1, df = 3,3; p = .001).

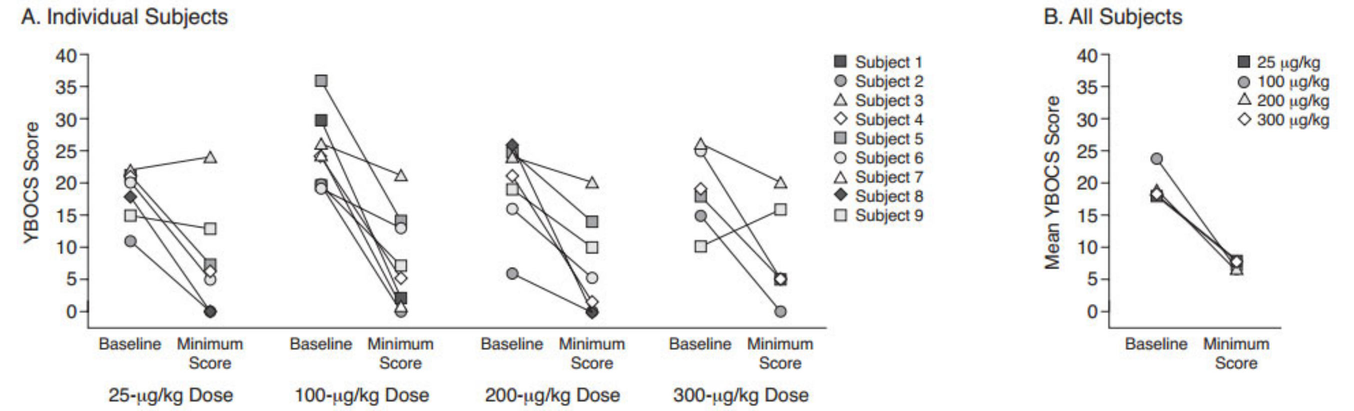

Figure 2. Comparison of Baseline to Minimum YBOCS Score During Testing[a]
[a]Baseline = score obtained immediately prior to ingesting psilocybin, minimum = lowest score observed (4, 8, or 24 hours) after ingestion of psilocybin.
Abbreviation: YBOCS = Yale-Brown Obsessive Compulsive Scale.

The HRS intensity subscale showed a significant linear main effect of dose (F = 12.36, df = 1,5; p = .017) (Figure 3). Total HRS score and every subscale with the exception of volition also showed a statistically significant linear main effect of dose. There were no significant correlations between HRS total or subscale scores and changes in OCD severity based on YBOCS or VAS scores.

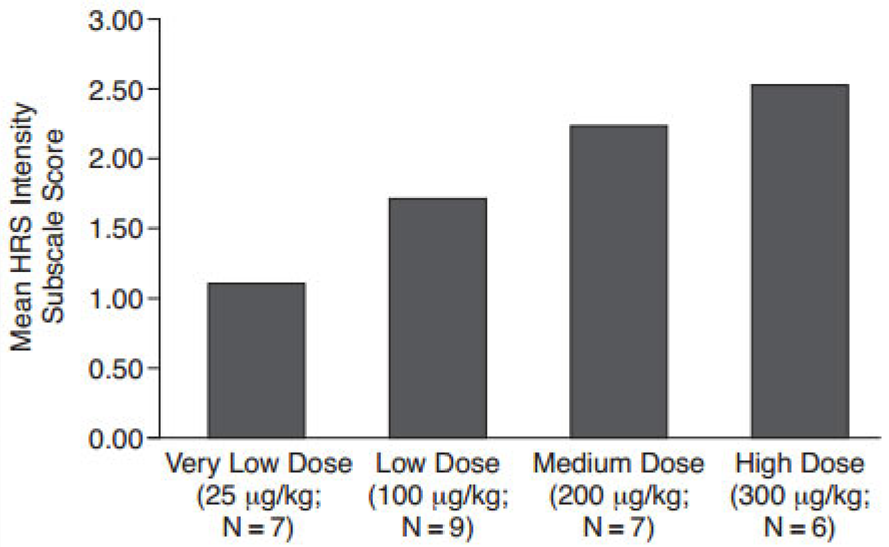

Figure 3. Relationship Between Psilocybin Dose and Intensity of Hallucinogenic Experience
Abbreviation: HRS = Hallucinogen Rating Scale.

OCD measurements were only obtained for up to 24 hours following psilocybin ingestion prior to the next session, and the duration of symptomatic improvement was not prospectively measured; however, 88.9% of subjects maintained a ≥ 25% decrease and 66.7% maintained a ≥ 50% decrease in YBOCS score at 24 hours with at least 1 of the testing doses. Two of the subjects reported that their symptomatic improvement lasted most of the following week after testing. Although there was a numerical difference between baseline scores at test 1 versus other test times, there was no statistically significant order effect when ANOVA with repeated measures was used (p = .133). One subject achieved long-term remission at the end of the 4 test sessions, as measured at 6- month follow-up.

Post hoc pairwise *t* test analysis comparing YBOCS scores during screening (25.2 ± 8.6) and baseline scores (24.1 ± 6.3) on test day 1 showed no statistical difference (p = .673), suggesting stability of YBOCS scores prior to psilocybin testing and the lack of anxiety-induced increase in YBOCS score prior to testing.

Conclusions

When administered in a supportive clinical environment, psilocybin appears to be safe and well tolerated. Psilocybin was associated with transient symptomatic reduction of OCD symptoms in subjects with treatment-resistant OCD.

These data result from a small proof-of-concept, phase I study designed to explore the safety for human consumption of 4 doses of psilocybin in a small sample of symptomatic OCD patients. The escalating dosing scheme was selected to allow exposure to increasingly higher doses only to individuals who had tolerated previous exposures. A smaller dose (VLD) was hypothesized to have negligible psychedelic effects and was introduced randomly at any time after the first dose. Subjects experienced stronger than anticipated response to this dose, as shown in Figure 3, and its clinical effects were also greater than anticipated. This response to VLD impedes the use of VLD as a placebo comparator, which clearly represents a major obstacle in our ability to explore clinical effects. Another methodological concern is the fact that the order of the doses was escalating, with the exception of VLD, which was inserted randomly and in double-blind fashion. This modified blind may have influenced expectations in both subjects and raters. Despite the obvious limitations from design and sample size, the data are suggestive of an acute benefit, worth exploring further.

Although we understand the psychedelic mechanism of action of psilocybin, it is not clear which specific receptors or pathways may mediate antiobsessional responses. It may be possible for subjects to experience a decrease in symptoms by the mere artifact of mindset and setting, which are known to affect the psychedelic experience in itself; by the contextual expectation of improvement; or just by the distracting psychedelic effects or a "pleasurable experience." It should be noted that to some of the patients the exposure to a psychedelic agent was perceived as a stressful event; for others, testing represented a time without access to the usual distractions that help reduce their obsessions; and for most, the overnight stay in the hospital represented a significant stressor. Therefore, the setting was ideal not for reduction of stress and obsessions, but rather for safety and monitoring purposes. This issue may have introduced selection bias by allowing participation by only those subjects who tolerated travel and overnight hospitalization.

There was, however, no clear dose-response relationship to the change in YBOCS score and no correlation of YBOCS score reduction to the perceived psychedelic intensity based on HRS total score or intensity subscale score.

Although the intent of this study was not to conduct psychedelic-facilitated therapy during testing, 5 of the subjects readily described their experiences as very psychologically and spiritually enriching. Four subjects reported during HD profound positive transcendental experiences such as exploration of other planets, visiting past-life reincarnations, and interacting with deities.

Most subjects reporting symptom reduction experienced a period of relief that extended beyond the pharmacologically expected life of the drug and beyond the 24-hour rating (see Figure 1). This lingering effect, which extends clearly beyond the "high" or psychedelic state, raises a number of intriguing mechanistic questions. For example, does the effect result from a residual feeling of well-being due to the experience of temporary symptom distraction or "pleasure," from the psychological insights described above, or from changes in working memory and attention as reported previously, or is the effect directly pharmacologically mediated? Although the explanation is highly speculative, if these are prolonged pharmacologic effects, they may be related to a rapid adaptive cascade of events such as postsynaptic 5-HT receptor down-regulation or early gene expression.

A large body of evidence supports the down-regulation of 5-HT$_{2A}$ receptors in response to hallucinogen administration in animal models and human subjects.[28] LSD has been reported to induce intracellular signal transduction changes that are different from endogenous 5-HT despite binding to the same receptor site.[29] In fact, LSD is reported to decrease gene expression in rat brain after single-dose administration, while no changes in expression of 5-HT$_{1A}$, 5-HT$_{2A}$, or 5-HT$_{2C}$ were observed.[30] These changes in gene expression, although reported with a similar compound rather than with psilocybin, may result in physiologic alterations that explain the delayed effect described above. It is also possible that the early changes in gene expression may be different after repeated administration of LSD or similar compounds, leading to the known downregulation of 5-HT_{2A}.[28]

Ingestion of psilocybin and similar substances will facilitate subjects' experiencing of altered states of consciousness and may lead to the development of powerful insights and profound existential and spiritual questions. Administration of these substances therefore should be approached with caution to minimize exposure to individuals who are vulnerable to psychosis or overvalued ideas. Researchers should carefully consider the subject's mindset prior to exposure, address concerns developed during the psychedelic experience through careful debriefing, and secure a source of supportive continuity afterward. In spite of these concerns, given that OCD is associated with a great deal of human suffering and societal burden, and that treatment-resistant OCD represents a valid indication for irreversible brain surgery, it may be reasonable to consider psilocybin, with its potential benefit, a less burdensome alternative and one worth investigating further.

In summary, this study confirms and extends anecdotal reports of acute reduction in OCD symptoms with exposure to psilocybin. Given the chronicity and disease burden of OCD and the high rate of insufficient response to currently approved treatments, future studies involving traditional blinded, randomized, placebo-controlled methodology should explore the efficacy of and duration of therapeutic benefit from a more prolonged exposure to repeated doses of psilocybin in patients with OCD.

Drug names: bupropion (Wellbutrin and others), clomipramine (Anafranil and others), desipramine (Norpramin and others), fluoxetine (Prozac and others).

The hallucinogenic serotonin 1A & 2A agonist psilocybin is known for its ability to induce illusions of motion in otherwise stationary objects or textured surfaces. This study investigated the effect of psilocybin on local and global motion processing in nine human volunteers.Using a forced choice direction of motion discrimination task we show that psilocybin selectively impairs coherence sensitivity for random dot patterns, likely mediated by high-level global motion detectors, but not contrast sensitivity for drifting gratings, believed to be mediated by low-level detectors.These results are in line with those observed within schizophrenic populations and are discussed in respect to the proposition that psilocybin may provide a model to investigate clinical psychosis and the pharmacological underpinnings of visual perception in normal populations.

Introduction

Like LSD and mescaline, the serotonergic (5-HT) hallucinogen psilocybin is renowned for its ability to temporarily alter an individual's conscious state. Known for causing visual disturbances, it is often reported that psilocybin causes surrounding objects and colours to appear brighter or clearer, with successively higher doses leading to illusions of motion and colour that can increase in complexity, resulting in elementary geometric and scenic hallucinations[1]. Although psilocybin binds to both 5-HT$_{2A}$ (k$_i$=6 nmol) and 5-HT$_{1A}$ (k$_i$=190 nmol) subtypes of serotonin receptors[2], recent evidence demonstrates that psilocybin induces visual distortions via 5-HT$_{2A}$ receptor activation[3]. Accordingly, this drug can be used to induce transient and predictable changes in neurotransmitter activity, in a controlled and selective manner, to gain insight into the mechanisms responsible for visual distortions associated with drug induced and schizophrenia related altered states of consciousness[4,5].

Vision is a fundamental component of the human conscious experience[6]. Consequently, an accurate characterization of where and how hallucinogens, such as psilocybin, influence different stages of visual perception could be beneficial on a number of counts. Given that psilocybin is known to induce illusions of motion, this study was designed to investigate two aspects of motion perception: contrast sensitivity for drifting gratings and coherence sensitivity for drifting random dot patterns. Evidence suggests that contrast sensitivity is limited by an early stage of visual processing, likely to be V1 itself[7,8]. However, the integration of local motion signals necessary for coherent thresholds is probably mediated by higher-level processes and is generally considered to involve the middle temporal area (MT or V5)[8-10]. Neural activity in this region shows strong motion opponency[11], increases linearly with motion coherence[12] and correlates closely with motion perception[13]. Because contrast sensitivity is thought to reflect early visual processes and motion coherence requires higher regions such as MT, the relative influence of psilocybin on these two visual processes can be used as an indication of the effect of this drug on different levels of cortical processing.

The primary aim of this study was to determine whether psilocybin impairs motion processing. A secondary aim was to investigate whether it does so with a selectivity similar to that seen in schizophrenic individuals, as this population has been shown to have deficits in local but not global motion processing[14]. Independent of clinical relevance, the final aim of this study was to use psilocybin's primary and preferential mode of action at 5-HT$_{2A}$ receptors to investigate a possible role of the serotonergic system in visual perception. This is of relevance because despite the common belief that the visual disturbances characteristics of hallucinogens are mediated predominantly via 5-HT receptors[3,15], to date, most research into the pharmacology of visual deficits in schizophrenic populations has tended to focus on dopamine[16,17].

Materials and Methods

Substance and dosing

Psilocybin was obtained through the Swiss Federal Office for Public Health. Psilocybin capsules (1mg and 5 mg) were prepared at the pharmacy of the Cantonal Hospital of Aarau, Switzerland and quality was controlled through tests for identity, purity and uniformity of content. The psilocybin dose (215 mg/kg) and lactose placebo were administered in gelatine capsules of identical appearance.

Subjects

Nine healthy volunteers (five male, four female) aged between 21 and 31 (mean 7 s.d.=27.172.6) were recruited through advertisement from the local university and technical college. After being informed by a written and oral description of the aim of the study, the procedures involved, and the effects and possible risks of psilocybin administration all volunteers were asked to give their written consent as a requirement of participation. All subjects had normal or corrected to normal vision and were healthy according to medical history, clinical examination, electrocardiography and blood analysis. They were also deemed by psychiatric interview to have no personal or family (first-degree relatives) history of major psychiatric disorder nor evidence for regular alcohol or substance abuse. Five of the participants reported having previous experience with psilocybin through the ingestion of psilocybe mushrooms; the other four were psilocybin-naïve. Subjects were reimbursed for their time and they were instructed that at any time they were free to withdraw from the study. The study was approved by the ethics committee of the University Hospital of Psychiatry, Zurich, and the use of psilocybin in humans was authorized by the Swiss Federal Office for public health.

Stimulus and procedure

Measures of contrast sensitivity were obtained using drifting gratings (Fig. 1). The stimulus comprised a 5 circular patch of vertical, sinusoidal grating with a spatial frequency of 1 cycle/deg, embedded in dynamic random noise. The grating was caused to drift leftwards or rightwards at 20 deg/s (10 Hz). Subjects were instructed to maintain fixation on a central fixation point and attend only to the direction of motion of the gratings within the patch while reporting the drift direction by pressing either the left or right arrow key of the keyboard.

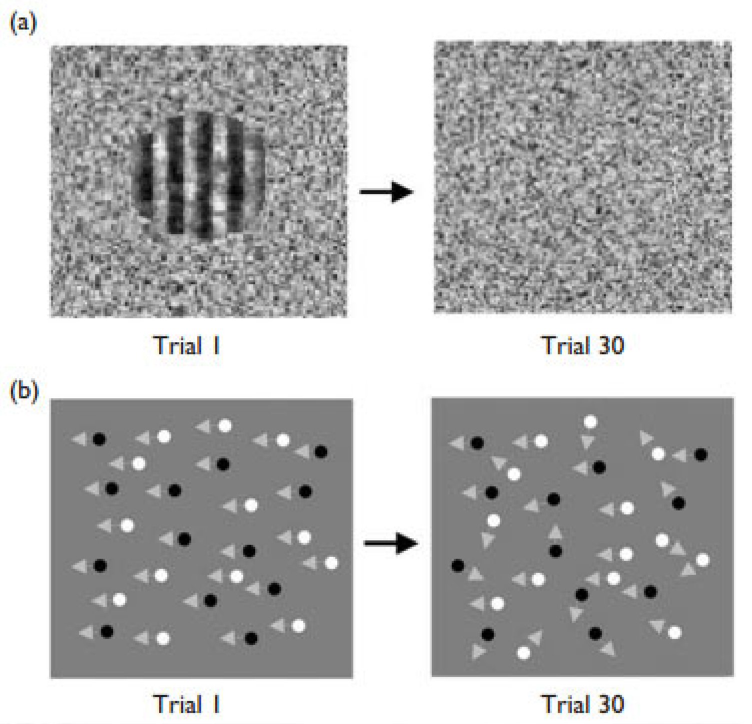

Fig. 1. Experimental stimuli.
(a) Visual contrast sensitivity was measured by asking subjects to report the direction of motion of a sinusoidal grating embedded within a background of noise. During the 30 trials of the session, the contrast of the gratings was reduced or increased adaptively, depending on whether or not the subject's response was correct. In this way a threshold estimate was calculated: the level of contrast at which motion direction identification was just possible.
(b) Coherence thresholds for global visual motion were measured with a random - dot pattern where a proportion of dots moved coherently, leftwards or rightwards, while the others were displayed at random.The ratio of coherent to randomly moving dots was varied from trial to home in on the threshold at which direction of motion was just detectable.

The gratings were generated in Matlab, using the Psychophysics Toolbox extensions[18,19] and presented on the screen for 400 ms (frame rate 100 Hz, mean luminance 30 cd/m^2). The contrast of the gratings was set initially to 30%, and then varied to home in on threshold using the adaptive QUEST algorithm[18,19]. Each session comprised 30 trials, and three sessions were run for each condition.

For the coherence thresholds, the stimuli comprised 100 small dots (each subtending 20' arc), half black and half white, generated by a C program running in DOS. A proportion of the dots were caused to drift leftwards or rightwards (20 deg/s), while the remainder of dots were displayed at random positions. Coherence thresholds (inverse of coherence sensitivity) were defined as the minimum proportion of coherently moving dots to produce 75% correct direction discrimination. Again, the stimulus was presented for 400 ms and coherence was varied from trial to trial by the QUEST algorithm, giving three separate estimates of threshold, each from 30 trials.

All stimuli were presented to subjects on a Sony Trinitron Multiscan E215 monitor and viewed from a distance of 60 cm within a dimly lit room. The final estimates of sensitivity for all conditions were calculated offline by fitting all data of a particular condition (90 trials) with cumulative Gaussian functions, and estimating the level of contrast or coherence to support 75% correct response.

Note that although the speed was matched for both types of stimuli (20 deg/s), the spatiotemporal characteristics were not identical: the stimuli for contrast sensitivity were narrow-band gratings, with a single spatial and temporal frequency (0.5 cycles/deg, 20 Hz), while the coherence stimuli were broadband random-dot patterns, with a range of temporal and spatial frequencies. The motivation for the choice of stimuli was that it was considered that narrow-band stimuli isolate better early motion mechanisms, whereas higher motion mechanisms have a broad range of spatial frequency selectivity[20].

Experimental design and statistical analysis

The study was double-blind, placebo-controlled, the order of dose assignment was counterbalanced and each experimental day was separated by at least 14 days. On each experimental day subjects were tested on all conditions prior to administration of psilocybin or placebo and then re-tested during the peak effect of the drug ~120 min after administration. In all sessions, subjects repeated the local and global motion discrimination tasks 3 times and the presentation order of these two tasks was sequentially alternated and counterbalanced. A repeated measures ANOVA was used to determine significance between the log sensitivity values for the respective drug conditions at pre-test and after 120 min for each of the two measures. In the case where significance was found, Tukey's *post-hoc* pair-wise comparisons were performed with $\alpha=0.05$.

Results

The geometric means for contrast and coherence sensitivity for pre-test and 120 min after drug intake, under both placebo (open bars) and psilocybin (grey bars) conditions are reported in Figure 2. With the contrast sensitivity for moving gratings, no significant time or drug effects were found ($F(1,8)=1.27$; p=NS). There was a slight reduction in average contrast sensitivity for the psilocybin condition at 120 min but the difference between this and the placebo condition was not statistically significant ($p=0.58$). However, the coherence sensitivities did show a significant effect of time and drug ($F(1,8)=7.39$; $p<0.05$). Subsequent post-hoc analysis revealed that the coherence sensitivity 120 min after psilocybin intake was significantly reduced from both the psilocybin pretest measure ($p=0.025$) and the corresponding 120 min placebo measure ($p=0.032$).

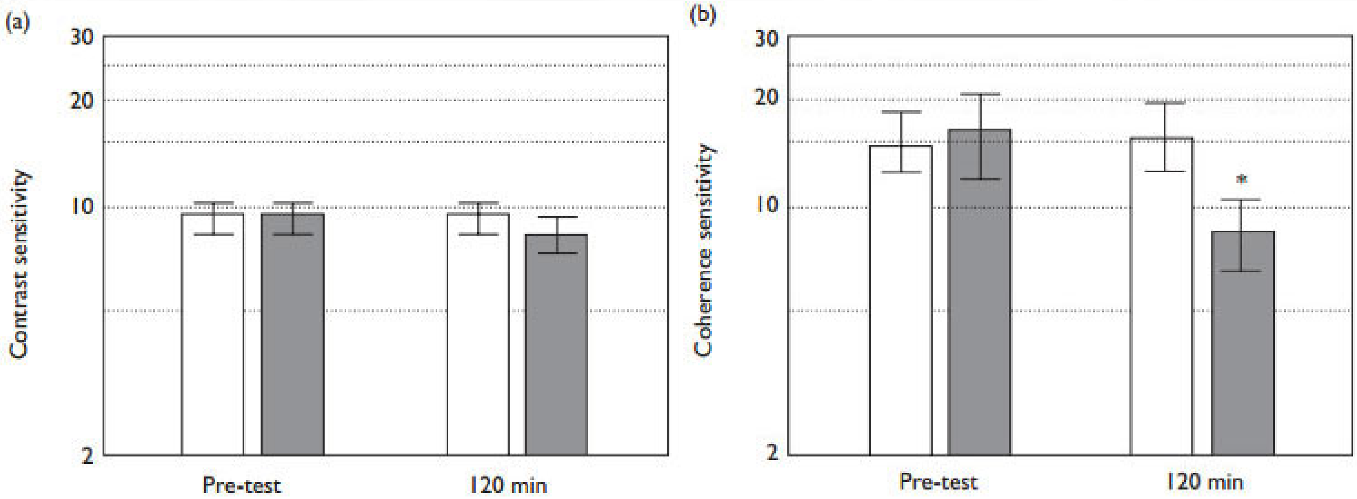

Fig. 2. Psilocybin administration was found to significantly reduce coherence but not contrast sensitivity. The two graphs illustrate the geometric mean for sensitivities at pre-test and peak state, tested 2 h after administration of either placebo (open bars) or psilocybin (grey bars), for (a) contrast and (b) coherence motion detection respectively. In the psilocybin condition, there is a significant reduction in global motion sensitivity in the 120 min peak condition compared with the pre-test level. No significant differences are observed in the placebo conditions. Error bars represent ± I s.e.; *$p<0.05$ level.

Figure 3 shows the individual results as a scatter plot, plotting the reduction in coherence sensitivity (ratio of placebo to psilocybin sensitivities) against the reduction in contrast sensitivities. While there is some scatter in the data, most points sit below the equality line (dashed), showing a greater effect for coherence than for contrast sensitivity. There was virtually no correlation (r^2=0.002) between the two estimates of sensitivity, consistent with the fact that one was affected and the other not.

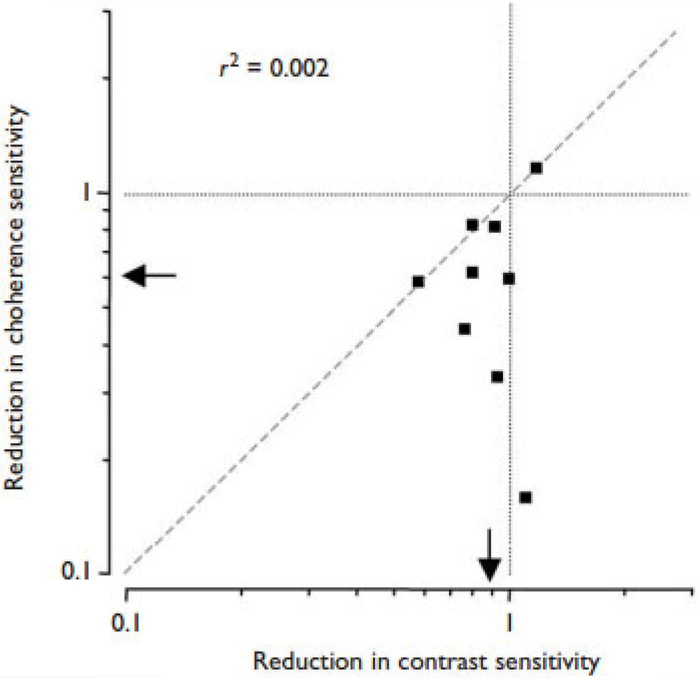

Fig. 3. Individual data showing reduction in relative sensitivity at the peak testing time for coherence sensitivity (ordinate) plotted against contrast sensitivity (abscissa). The estimates of sensitivity reduction were calculated as the ratio of placebo to psilocybin sensitivity in the 120 min peak condition. The arrows show the respective mean reduction in sensitivity. The vertical and horizontal dashed lines passing through unity correspond to no drug effect, while the diagonal line indicates equal effect for the two conditions. Most points pass below this line, indicating greater reduction of coherence than contrast sensitivities.

Discussion

Here we show that a 215 mg/kg dose of the 5-HT$_{1A\&2A}$ agonist psilocybin selectively impairs global motion, but not local motion processing in humans. Current evidence suggests that local motion discrimination is resolved at the level of V1[7,8], while the integration of local motion signals necessary for global motion discrimination is believed to be dependent on higher processing areas such as MT[8,12].

Consumption of psilocybin, in doses similar to those used in the current study, often results in visual and cognitive disturbances (for a detailed psychometric report see[1]). In this study subjects were encouraged to report their subjective impressions, prior to and after the experimentation. Some reported that surfaces appeared to pulsate in depth or acquire a texture comprising intricate dynamic patterns. Many reported that objects themselves were seen to sway or to protrude further into their surrounding space. Beyond a general warping of perspective, however, the gross spatial organisation of objects and their surrounds remained stable relative to the observer. For example, a plant situated in the corner of the room may appear to be dancing or growing towards the viewer and the room itself may shrink or expand but the room will not spin around the observer nor would the plant appear to hover in space or move to the other side of the room. Subjects reported that the computer keyboard and monitor generally remained stable while dynamic textures and patterns would sometimes be seen both within the background grey component of the display and the target stimulus. Some subjects also reported the stimulus to be flickering. All these reports are in general agreement with previous studies using similar doses[1].

Based on converging evidence it has been suggested that psilocybin-induced altered states of consciousness may provide a model through which to investigate clinical symptoms of psychosis such as those common to schizophrenia[5]. In support of this proposition, our results are in line with previous work showing that schizophrenic individuals are impaired in coherent but not local motion processing, compared to normal populations[14]. Given that psilocybin is known to show relative selectivity as an agonist at the 5-HT$_{1A\&2A}$ receptor sites, this result raises questions regarding the assertion that the motion perception deficits observed in schizophrenic patients are due to differential activation of the dopamine D2 receptor within this population[16]. As both neurotransmitter systems are commonly targeted in anti-psychotic medication, it is important that the relative influence of these transmitters is understood if optimal anti-psychotic medications are to be designed in the future.

In addition to the observed drug induced reduction in coherent motion sensitivity, the fact that psilocybin did not significantly affect local motion contrast sensitivity is a valuable result in itself. First, it shows that subjects were still capable of attending to the stimulus and accurately reporting their perception, whist under the influence of psilocybin. Second, because local motion discrimination is believed to be a relatively low-level process resolvable at the level of V1, the lack of effect on local motion thresholds indicates that the visual disturbances and hallucinations associated with this drug are unlikely to reflect changes either at the retinal level or in the transfer of information from the retina through the lateral geniculate nucleus (LGN) to primary visual cortex.

It is currently unclear to what degree psilocybin effects the vestibular system and this is an additional area that may be worth investigating in the future, particularly in light of a recent paper by Jeong *et al*. indicating that vestibular nuclei may be activated by the 5-HT2 receptors[21]. However, given that subjects had no trouble moving around their environment and the experimenter observed no evidence of nystagmus or any other systematic changes in eye movements, it seems unlikely that the illusions of motion described here result from vestibular dysfunction. Furthermore, the reported illusions of motion were confined to specific objects, not gross translations of the whole visual field, or sensations of self motion, as would be expected from disturbance of the vestibular system.

As a number of subjects commented that subjectively the global motion task became harder due to an increased salience of the randomly moving dots, one avenue for future research is the question of whether the coherent motion deficit induced by the psilocybin reflects a reduction in sensitivity to motion signals or reduced inhibition of the non-coherent motion signals. Further investigation of this distinction between reduced sensitivity to the motion signals of interest, as opposed to a reduction of inhibition of the noise (increasing the interference/distraction) caused by the non-coherent motion, is of particular relevance given the hypothesized role of sensorimotor gating deficits in schizophrenia[5].

Because the stimulus presentation time in the current study was 400 ms, an alternative explanation to be considered is that psilocybin causes a reduction in temporal integration. It has been shown that for local motion processing, performance improves linearly as stimulus presentation increases up until about 200 ms, whereas for global motion processing performance continues to improve with increased stimulus exposure durations of up to 3 s[22]. It is possible that psilocybin acts to reduce this limit in a similar way that it is known to vary with attentional load[23]. The issue of temporal integration is worthy of further investigation as it is of relevance to the observed motion processing deficits in clinical populations, as well as the psilocybin induced effects reported here.

To date, investigations into visual consciousness has focused on identifying the aspects of neural activity which correlate with perception, whilst little attention has been paid to understanding the integral role of the neurotransmitters in modulating this neural activity. This work illustrates that drugs that transiently alter an individual's visual perception may offer one means to explore the pharmacological processes underlying vision and redress this imbalance.

Background: Previous studies indicate that mismatch negativity (MMN)-a preattentive auditory event-related potential (ERP)-depends on NMDA receptor (NMDAR) functioning. To explore if the strength of MMN generation reflects the functional condition of the NMDAR system in healthy volunteers, we analyzed correlations between MMN recorded before drug administration and subsequent responses to the NMDAR antagonist ketamine or the 5-HT$_{2A}$ agonist psilocybin.

Methods: In two separate studies, MMN was recorded to both frequency and duration deviants prior to administration of ketamine or psilocybin. Behavioral and subjective effects of ketamine and psilocybin were assessed with the Brief Psychiatric Rating Scale and the OAV Scale-a rating scale developed to measure altered states of consciousness. Correlations between ERP amplitudes (MMN, N1, and P2) and drug-induced effects were calculated in each study group and compared between them.

Results: Smaller MMN to both pitch and duration deviants was significantly correlated to stronger effects during ketamine, but not psilocybin administration. No significant correlations were observed for N1 and P2.

Conclusions: Smaller MMN indicates a NMDAR system that is more vulnerable to disruption by the NMDAR antagonist ketamine. MMN generation appears to index the functional state of NMDAR-mediated neurotransmission even in subjects who do not demonstrate any psychopathology.

Introduction

Mismatch negativity (MMN) is an auditory event-related potential (ERP) indexing preattentive detection of stimulus deviance (Näätänen 1995). It is automatically generated with a latency of 100 to 200 ms after the presentation of a stimulus that deviates in one of its physical dimensions (pitch, intensity, duration, location) from preceding frequently repeated standard stimuli (Näätänen 1995; Novak *et al*. 1990; Ritter *et al*. 1995). Mismatch negativity is thus the manifestation of a preattentive process that compares the deviant stimulus to the sensory memory trace of the standard stimulus (Näätänen 1990; Novak *et al*. 1990; Ritter *et al*. 1995).

Mismatch negativity-like activities can also be recorded in animals and thus are amenable to investigations of its underlying neurobiological substrate (Csépe *et al*. 1987; Javitt *et al*. 1994; Javitt *et al*. 1996). Studies in monkeys and cats show that MMN specifically involves activation of the supragranular layer of the primary and secondary auditory cortices (Karmos *et al*. 1998; Javitt *et al*. 1994; Javitt *et al*. 1996). It has been hypothesized that this activation involves excitation of pyramidal neurons as a net result of two processes: 1) reduction of tonic inhibition (disinhibition) due to stimulation by the standard tone, and 2) excitation of NMDA receptor (NMDAR) in response to the deviant stimulus (Schroeder *et al*. 1997; Karmos *et al*. personal communication; Javitt *et al*. 1996). NMDAR functions are uniquely sensitive to membrane potential (Cotman *et al*. 1995); thus, the magnitude of stimulation-induced current flow through NMDAR depends upon the degree of neuronal disinhibition. This property makes the NMDAR uniquely suited for mediating conditional responses such as MMN. Studies in monkeys have indeed demonstrated that intracortical and systemic application of NMDAR antagonists selectively abolishes MMN-like activities without affecting such sensory ERPs as N1 (Javitt *et al*. 1996; Javitt *et al*. 1994). In addition, we recently demonstrated that ketamine, a noncompetitive NMDAR antagonist, selectively impairs MMN generation in humans without reducing sensory ERPs (Umbricht *et al*. 2000). Furthermore, ketamine significantly reduced the magnetic counterpart of MMN, MMNm, in healthy volunteers (Sauer *et al*. 2000). The NMDAR antagonist nitrous oxide (N2O) (Jevtovic-Todorovic *et al*. 1998) has also been reported to induce a significant reduction of MMN (Pang *et al*. 1999). In contrast, the psychotomimetic psilocybin does not significantly affect MMN in healthy volunteers, although it reduces N1 (Umbricht *et al*. 2001).

Psilocybin (O-phosphoryl-4-hydroxy-*N*,*N*-dimethyltryptamine) - a naturally occurring indoleamine hallucinogen- is readily metabolized to psilocin after ingestion (Hasler *et al*. 1997). In rats, psilocin binds with high affinity to the 5-HT$_{2A}$ (Ki = 6.0 nM) and with moderate affinity to the 5-HT$_{1A}$ receptor (Ki = 190 nM) (McKenna *et al*. 1990). Although indoleamine hallucinogens bind to various subtypes of serotonin receptors, the hallucinogenic and cognitive effects are primarily believed to be mediated through agonist action at the 5-HT$_{2A}$ receptor (Aghajanian *et al*. 1999a, Vollenweider *et al*. 1998). Moreover, the affinity of indoleamine hallucinogens at the 5-HT$_{2A}$ receptor is highly correlated with their hallucinogenic potency in humans (Aghajanian *et al*. 1999a).

In summary, the available evidence strongly indicates a central role of the NMDAR in MMN generation. Thus, deficits in MMN generation as observed in such neuropsychiatric disorders as schizophrenia (Catts *et al*. 1995; Javitt *et al*. 1995; Umbricht *et al*. 1998) may be a manifestation of deficient NMDAR-dependent neurotransmission (Olney *et al*. 1995; Javitt *et al*. 1991).

Furthermore, these data suggest that even in non-patient subjects the strength of MMN generation may reflect the functional condition of NMDAR systems. To explore this hypothesis, we examined the correlations between MMN recorded prior to drug administration and psychosis-like experiences and behavioral effects induced by the subsequent administration of ketamine or the psychotomimetic psilocybin. Ketamine, and to a lesser extent psilocybin, can induce signs and symptoms in healthy volunteers that mimic some psychotic symptoms of schizophrenia (Krystal *et al*. 1994; Vollenweider *et al*. 1998). Thus, we hypothesized that if the strength of MMN indeed reflects the functional condition of the NMDAR system (i.e., its efficiency or redundancy), then the effects of ketamine should be more disruptive. (i.e., stronger in a subject with a smaller MMN at baseline). In other words, an inverse correlation between baseline MMN and ketamine-induced psychosis-like experiences should exist. On the other hand, such a correlation should not be observed between MMN and the effects of psilocybin.

To test this hypothesis, data from two separate studies on the effects of ketamine and psilocybin in healthy volunteers were analyzed. The main goal of both studies was to assess the effects of ketamine or psilocybin, respectively, on MMN generation. The results of these studies have been (Umbricht *et al*. 2000) or will be reported elsewhere (Umbricht unpublished). Here, we only report on the session with active drug administration (ketamine infusion or psilocybin administration, respectively).

Methods and Materials

Data from two separate studies of effects of ketamine and psilocybin in healthy volunteers (ketamine study: N = 20, M/F = 14/6, mean age = 24.6 ± 2.9 y; psilocybin study: N = 18, M/F = 10/8, mean age = 25.1 ± 4.3 y) were analyzed. The details of the methodology-identical in many aspects for both studies-have been published previously (Umbricht *et al*. 2000). Both studies had been approved by the ethics committee of the Psychiatric University Hospital Zurich. Briefly, prior to study entry, all subjects underwent a detailed screening to ensure the absence of any personal or family psychiatric history and signed informed consent after having been informed in detail about the study and the expected drug effects. Subjects underwent two sessions (placebo/active drug) in counterbalanced and randomized order in both studies. Ketamine was administered intravenously (a bolus dose of 0.24 mg/kg was given over 5 min, then a maintenance ketamine infusion at 0.9 mg/kg/hour was started after a pause of 5 min). Psilocybin was given po at a dose of 0.28 mg/kg. Here, were only report on aspects of the active drug session.

In each session, EEG recordings were acquired with a Neuroscan Scan system (Neuroscan Labs; Sterling Virginia) and obtained from 28 scalp locations, consisting of standard 10/20 placements plus right and left mastoid placements, along with right vertical and horizontal EOG electrodes. An electrode placed on the nose served as reference. Electrode impedance was kept below 5 kΩ. The sampling rate was 500 Hz.

Auditory stimuli consisted of 100 ms, 1000 Hz standard intermixed with 100 ms, 1500 Hz pitch deviants and 250 ms, 1000 Hz duration deviants. Stimuli were presented in a fixed order (nine standards, one pitch deviant, nine standards, one duration deviant) with stimulus onset asynchrony of 300 ms presented through foam insert earphones at a nominal intensity of 75 dB SPL. Rise/fall time was 5 ms for all stimuli. Stimuli were presented in four blocks with a total of 1517 stimuli. During presentation of the auditory test paradigm, subjects performed a visual AX-Continuous Performance Task.

For the analyses of the auditory ERPs, epochs with a 100-ms prestimulus baseline and a 500-ms poststimulus interval were constructed. After correction of horizontal eye movements and blinks, epochs with amplitudes that exceeded ± 75 µV at any electrode except the vertical eye leads were excluded from further averaging. Following artifact rejection, epochs were averaged offline for each subject and stimulus type and were digitally filtered with a low-pass filter of 15 Hz (24 dB down). Analyses focused on N1 and P2 to the standard stimuli and MMN generation to pitch and duration deviant stimuli as measured at electrode Fz. The N1 amplitude was measured as peak negativity within the 50 to 150 ms latency; P2 amplitude as peak positivity within the 150 to 250 ms latency. Mismatch negativity to pitch deviants was measured as peak negativity within the 100 to 225 ms latency window and MMN to duration deviants within the 200 to 300 ms range in the difference waveforms (deviant minus standard waveforms; see Figure 1). Waveforms were mathematically referenced to an average-mastoid reference prior to peak detection.

Drug-induced signs and symptoms were assessed both with an observer administered rating scale, the Brief Psychiatric Rating Scale (BPRS) (Overall *et al*. 1962), and with a self-rating scale (the OAV questionnaire [Dittrich 1998]). An anchored version of the BPRS with scale points of 1 to 7 was used (Woerner *et al*. 1988). For this analysis, the BPRS total score and the BPRS psychosis factor score (sum of the items "conceptual disorganization", "suspiciousness," "hallucinatory behavior," "unusual thought content") were used. Although the BPRS has been used previously (Krystal *et al*. 1994; Anand *et al*. 2000) to assess drug-induced psychotic symptoms in healthy volunteers, it was not developed and validated for that purpose and thus may not capture some of the more subtle effects induced by psychotomimetics. For this reason, we chose to use the OAV questionnaire as an additional assessment. The OAV questionnaire is a visual analog scale version of the APZ questionnaire that has been well validated as a tool to measure altered states of consciousness (Dittrich 1998; Bodmer *et al*. 1994). It contains three factor-analytically derived subscales: "Oceanic Boundlessness (OSE)" "Dread of Ego Dissolution (AIA)" and "Visionary Restructuralization (VUS)." "Oceanic Boundlessness" describes a positive state similar to mystic experiences. "Dread of Ego Dissolution" reflects an unpleasant state characterized by anxiety, feelings of being disconnected from the surroundings, and not in control of one's own thoughts. "Visionary Restructuralization" refers to illusionary experiences, ideas of reference, and changes in the meaning of things. Subjects were asked to fill out this questionnaire on the evening after each study session. All subjects in the ketamine study and 16 subjects in the psilocybin study returned completely filled out questionnaires after the active drug session. Statistical analyses were thus performed with the data from these subjects.

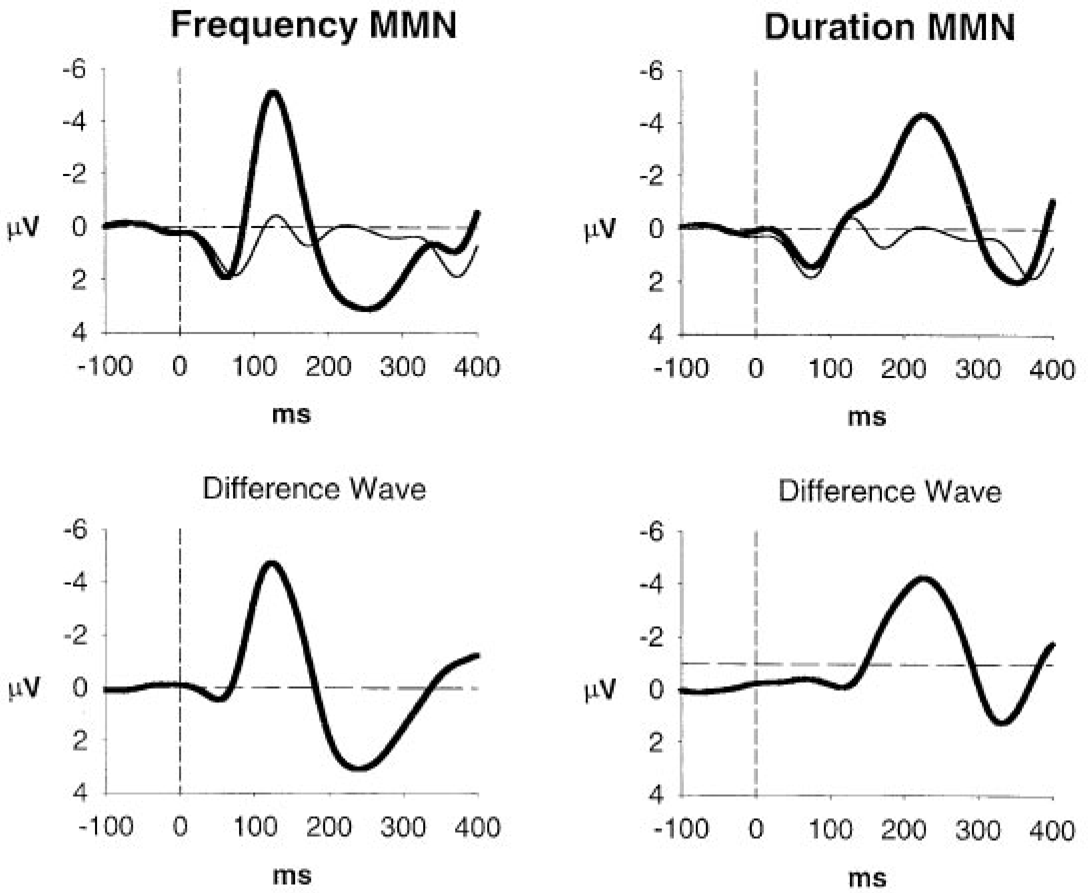

Figure 1. ERPs to standard stimuli (thin line, both panels upper row) and frequency deviants (thick line, left panel, upper row) and duration deviants (thick line, right panel, upper row). Difference waves (ERP to deviant stimuli minus ERP to standard stimuli) are presented in the lower row (left panel: frequency deviant condition; right panel: duration deviant condition). MMN amplitudes were measured in these differences waves.

Pearson product correlations were calculated between ERP measures (amplitudes of N1, P2, mean MMN, and MMN to frequency and duration deviants individually) and the behavioral measures (BPRS total score, BPRS psychosis factor score, OAV total score and its three factors) separately for the ketamine and the psilocybin study. Correlations were compared between groups using ANOVAs with the behavioral measures as dependent variable, group membership (drug) coded as dummy variable, and the ERP measure as covariate. Alpha levels of .05 were considered significant.

Results

Both ketamine and psilocybin administration induced robust behavioral effects as evidenced in significant increases of the BPRS total and the BPRS psychosis factor scores and strong subjective effects as rated on the OAV questionnaire (see Table 1). The increase of the BPRS total and psychosis factor score was greater during ketamine than psilocybin administration. The difference of the BPRS psychosis factor score was significant (t = 3.15, df = 35, $p < .05$). However, the subjectively rated effects of ketamine and psilocybin as assessed by the OAV scale and its three factors were not significantly different (see Table 1).

The peak amplitudes and latencies of N1, P2, and MMN to pitch and duration deviants prior to drug administration did not differ between subjects in the ketamine study and those in the psilocybin study (see Table 2). In the ketamine study, the mean MMN amplitude prior to drug administration correlated significantly with the BPRS total score, the OAV total score, and its three factor scores (see Table 3). Subjects with smaller amplitudes experienced stronger effects during ketamine administration. Examining MMN to frequency and duration deviants separately, we observed significant correlations between MMN to duration deviants and OAV total score and its three factors (see Table 3 and Figure 2). The correlation with the BPRS total score did not reach significance. Similarly, the correlations between MMN to frequency deviants and OAV total scores and the OSE and VUS factors were significant, while the correlation with the BPRS total score dropped below significance level. In contrast, in the psilocybin study, no significant correlations between mean MMN or separate MMNs and any of the behavioral measures were observed; however, only the correlation between mean MMN and total OAV score was significantly greater in the ketamine than the psilocybin group (see Table 3).

Table 1. OAV and BPRS Scores during Ketamine and Psilocybin Administration.

	Ketamine		Psilocybin		
	Mean ± SD	Range	Mean ± SD	Range	Significance

The F values and significance levels are given for the interaction of drug ERP measure in an univariate ANOVA with the behavioral measure as dependent variable, group membership (drug) as the independent factor and the ERP measure as covariate. A significant value for the interaction indicates that the correlations are significantly different in the two groups.

MMN - Mismatch negativity
AIA - Dread of Ego Dissolution
OSE - Oceanic Boundlessness
VUS - Visionary Restructuralization
BPRS - Brief Psychiatric Rating Scal

[a] $df = 1.30$
[b] $p < 0.001$ (2-tailed)
[c] $p < 0.005$ (2-tailed)
[d] $p < 0.05$ (2-tailed)
[e] $p < 0.1$ (2-tailed)

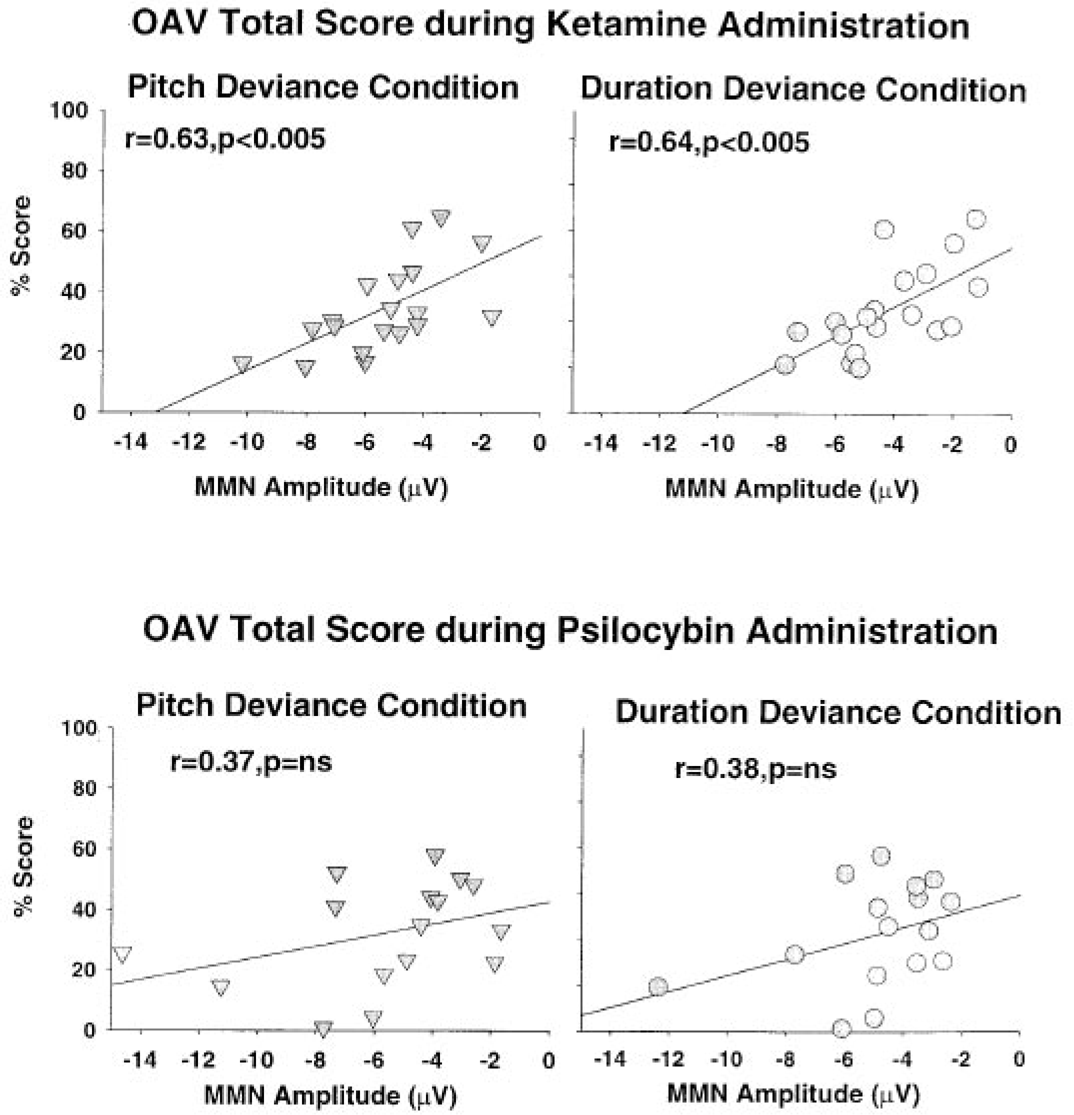

Figure 2. Scatterplot of MMN to pitch or duration deviants prior to drug administration and subjective experiences during ketamine (upper panel) or psilocybin administration (lower panel) as assessed by the OAV self-questionnaire. The OAV rating is expressed as percentage of the maximum points possible.

Peak amplitudes of neither N1 or P2 were significantly correlated with any behavioral measure both in the ketamine and the psilocybin studies.

Discussion

Previous studies have demonstrated that the auditory event-related potential MMN is significantly reduced or abolished by NMDAR antagonists in humans and nonhuman primates, indicating a role of the NMDAR in its generation (Umbricht *et al*. 2000; Javitt *et al*. 1996; Sauer *et al*. 2000; Pang *et al*. 1999). We recently reported that ketamine significantly reduced MMN in healthy volunteers (Umbricht *et al*. 2000). In this additional study, we explored the hypothesis that MMN in these healthy volunteers - recorded prior to drug administration - should therefore correlate with psychosis-like behavioral effects and experiences induced by subsequent administration of the NMDAR antagonist ketamine. Indeed, we found strong correlations between the magnitude of MMN in a baseline condition and subjectively rated ketamine-induced effects, whereas the clinician-rated effects showed weaker correlations albeit in the right direction. In contrast, in the psilocybin study, none of the corresponding correlations reached significance. Furthermore, significant correlations were only observed with MMN amplitudes, but not between the effects of ketamine and the amplitudes of the sensory ERPs N1 and P2 (i.e., with those ERPs that are thought to depend less on NMDAR functioning, and indeed are not diminished by NMDAR blockade in humans) (Umbricht *et al*. 2000). Thus, our findings lend some support to our hypothesis that the strength of MMN generation as expressed in its amplitude reflects the resilience of the NMDA system to perturbation by an acute administration of NMDAR antagonists. It has been previously demonstrated that the relative affinity of (S)- and (R)-ketamine enantiomeres at the NMDAR complex correlates with the degree of psychosis-like experiences (Oye *et al*. 1992; Vollenweider *et al*. 1997). The magnitude of pharmacologically induced deficits in NMDAR-dependent functions is therefore reflected in the magnitude of psychosis-like symptoms. Conversely, stronger psychosis-like effects at the same dose of NMDAR antagonist are likely reflecting a greater disruption in NMDAR-dependent neurotransmission. Given the correlation of MMN with the psychosis-like effects of ketamine, MMN- recorded in a normal state of consciousness-can thus be regarded as an in vivo indicator for the vulnerability to disruption of NMDAR-dependent systems. Thus, MMN provides some information about the functional "condition" of NMDAR-mediated neurotransmission: a smaller MMN indicates a less resilient or less redundant NMDAR system; such a system is also more perturbed by NMDAR antagonist given at comparable doses. The fact, however, that similar, albeit weaker, correlations were observed in the psilocybin study that-with the exception of the correlation between mean MMN and total OAV-were not significantly different from the corresponding correlations in the ketamine study indicates that a smaller MMN may also manifest a general vulnerability to the effects of psychotomimetics. Interestingly, both NMDAR antagonists and 5-HT$_{2A}$ receptor agonists induce excessive glutamate release, thus sharing a final common pathway that has been suggested to account for their overlapping cognitive and psychotomimetic effects (Aghajanian *et al*. 2000; Aghajanian *et al*. 1999b; Moghaddam *et al*. 1997; Moghaddam *et al*. 1998). In addition, both NMDAR antagonists and 5-HT$_{2A}$ agonists lead to excessive dopamine release in humans (Kegeles *et al*. 2000; Breier *et al*. 1998; Vollenweider *et al*. 2000; Vollenweider *et al*. 1999). In other words, both compounds appear to induce abnormalities in the dynamics of these neurotransmitter systems. It is conceivable, but speculative, that the functional state of the NMDARs may modulate the effects of 5-HT$_{2A}$ agonists on glutamate and dopamine release. In such a scenario, the magnitude of MMN as an indirect expression of NMDAR functioning would be expected to show some correlation with 5-HT$_{2A}$ agonist-induced effects. The results of our study are consistent with such a view.

We used the analog scale version of the APZ questionnaire (Dittrich 1998; Bodmer *et al*. 1994) to assess the drug-induced subjective effects. While less known than the BPRS, this scale was specifically developed and validated to measure drug-induced states of altered consciousness in healthy subjects; however, in a recent study, schizophrenic patients rated the OAV questionnaire as a moderate to very good instrument for the assessment of their psychotic experiences (Gouzoulis-Mayfrank *et al*. 1998). Furthermore, a principal component analysis revealed a similar three-factor structure in schizophrenic patients as in altered states of consciousness in healthy volunteers, supporting the observation that symptoms induced by psychotomimetics in healthy subjects resemble psychotic symptoms of schizophrenia. In addition, the total OAV score was found to correlate significantly with the score on the BPRS thought disorder factor. Thus, these findings strongly suggest that subjectively rated drug-induced effects in healthy volunteers are similar to genuine psychotic experience. The use of this self-rating scale permits to capture drug effect in a detailed way that does not always seem possible with the BPRS that focuses on some key psychotic symptoms, but may fail to assess more subtle effects, particularly in subjects who become completely withdrawn and mute. This may explain why the correlations of MMN and BPRS scores were weaker in our study.

This study has several limitations. We did not obtain blood levels of ketamine and psilocin, the main active metabolite of psilocybin. Even though we used the same dose per kilogram body weight for each person, it is conceivable that the actual concentration of ketamine and psilocybin and their psychoactive metabolites at the receptor differed between subjects, thus accounting for the differently strong subjective effects. Yet, since MMN was recorded prior to drug administration, such a possibility can hardly explain our findings unless one postulates rather implausible correlations between strength of MMN generation and factors influencing the metabolism of ketamine and psilocin or their transfer through the blood brain barrier. Secondly, the number of subjects available for analysis of the subjectively rated effects was lower in the psilocybin study, thus reducing the power to find significant correlations in this group. Thirdly, we performed multiple correlational analyses, thus inflating the probability of type-I errors; however, the overall pattern of significant correlations (only between MMN and behavioral effects and only in the ketamine study) would argue against our results being a chance finding.

In conclusion, the results of our study suggest that MMN in a normal state of consciousness is an indicator for the vulnerability to disruption of NMDAR-dependent systems in healthy volunteers. Smaller MMN manifested a state that was more vulnerable to disruption and, thus, functionally closer to a deficient NMDAR system. MMN generation appears to index the functional state of NMDAR-mediated neurotransmission, even in subjects who do not demonstrate any psychopathology. MMN may thus become a useful tool in studies on

NMDAR functioning in humans.

PSILOCYBIN, an indoleamine hallucinogen, produces a psychosis-like syndrome in humans that resembles first episodes of schizophrenia. In healthy human volunteers, the psychotomimetic effects of psilocybin were blocked dose-dependently by the serotonin-2A antagonist ketanserin or the atypical antipsychotic risperidone, but were increased by the dopamine antagonist and typical antipsychotic haloperidol. These data are consistent with animal studies and provide the first evidence in humans that psilocybin-induced psychosis is due to serotonin-2A receptor activation, independently of dopamine stimulation. Thus, serotonin-2A overactivity may be involved in the pathophysiology of schizophrenia and serotonin- 2A antagonism may contribute to therapeutic effects of antipsychotics. *NeuroReport* 9: 3897-3902

Introduction

The dopamine (DA) hypothesis of schizophrenia has emphasized that a dopaminergic dysbalance is critical in the pathophysiology and treatment of schizophrenia. Increasing evidence, however, suggests that serotonin (5-HT) may also be implicated. Support for an involvement of the serotonin system stems from observations that schizophrenia patients show alterations in cortical serotonin receptor binding; novel atypical antipsychotics have potent antagonistic action at 5-HT$_2$ receptors; and classic indoleamine hallucinogens, which interfere with the serotonin system, can elicit schizophrenia-like symptoms in humans (for a review see Ref. 1).

Psilocybin (O-phosphoryl-4-hydroxy-*N*,*N*-dimethyltryptamine) in particular, a natural indoleamine hallucinogen, has been reported in extensive studies to produce a clinical syndrome that resembles in certain respects the first manifestation of schizophrenic decompensation[1,2] Ego-disorders,[2,3] affective changes,[2] loosened associations4 and perceptual alterations are especially common features of psilocybin-induced and early acute schizophrenic stages.[1,2,5,6] Similar findings have also been reported for the structurally related indoleamine hallucinogen lysergic acid diethylamide (LSD), when the comparison involved early, as opposed to chronic, schizophrenics.[7] Consistent with this suggested clinical similarity, we recently found that psilocybin in normal subjects produced a marked prefrontal activation associated with ego- and thought disorder[3] comparable to that seen in acutely ill unmedicated or first episode schizophrenics.[8]

After ingestion, psilocybin is immediately dephosphorylated to psilocin (4-hydroxy-*N,N*-dimethyltryptamine), [9] which is closely related in chemical structure to serotonin (5-hydroxytryptamine, 5-HT). Psilocybin and LSD also share similarities in psychological effects in humans and in neurochemical actions in animals with phenalkylamine hallucinogens, such as 2,5-dimethoxy-4-iodoamphetamine (DOI.[10] Both indole and phenalkylamine hallucinogens bind primarily to 5-HT$_1$, 5-HT$_2$, 5-HT$_5$, and 5-HT$_7$ receptors.[11] The common effects of these hallucinogens may be mediated by agonist actions at 5-HT$_2$ receptors,[12] since the potency of hallucinogens in humans correlates well with 5-HT$_2$ receptor binding affinity in animals,[13] and the behavioral[14] and electrophysiological[15] effects of hallucinogens in animals can be blocked by 5-HT$_2$ antagonists. Although these animal data suggest a contribution of the 5-HT$_2$ receptor system in hallucinogenic drug action, there are, however, some difficulties with interpreting the mechanism of action of these drugs. First, data from animal studies are difficult to extrapolate to humans, so animal models of hallucinogenic drug action may not reliably predict hallucinogenic properties in humans. Second, LSD has also been reported to stimulate dopamine receptors, suggesting a possible involvement of dopamine in LSD psychosis.[16] Third, psilocybin, although it displays no activity at dopamine receptors,[16] might well modulate the dopamine systems through interactions of central serotonin and dopamine systems.[10] Thus, it remains unclear whether psilocybin and LSD mediate their psychological effects in humans via 5- HT$_2$ receptor stimulation alone or a subsequent activation of the dopamine systems, or both. Given the suggested importance of 5-HT$_2$ receptors in schizophrenia and mechanism of action in antipsychotics, it is important to further investigate the role of 5-HT$_2$ receptors in psychotic symptom formation.

To test the hypotheses that 5-HT$_2$ and/or DA D2 receptors contribute to psychological effects of indoleamine hallucinogens in humans, we studied the influence of pretreatment with the 5-HT$_2$ antagonist ketanserin,[17] the D2 antagonist and typical antipsychotic haloperidol,[18] or the mixed 5-HT$_{2/D2}$ antagonist and atypical antipsychotic risperidone[18] on the psychotomimetic effects of psilocybin in normal subjects, using a placebo-controlled, within-subject design. The Altered State of Consciousness rating scale (APZ-OAV) was used to assess the psilocybin-induced clinical syndrome because it validly measures changes from the normal waking state independently of the etiology of those changes.[19] In addition, based on our previous metabolic findings in psilocybin subjects,[3] we have hypothesized that psilocybin may lead to working memory deficits as seen in schizophrenic patients.[20] A visual-manual delayed response task (DRT) was used to measure possible drug-induced alterations in reaction times indicative of spatial working memory deficits.[20]

Materials and Methods

The study was approved by the Ethics Committee of the Psychiatric University Hospital Zürich and the use of psilocybin by the Swiss Federal Health Office (BAG), Department of Pharmacology and Narcotics (DPN), Bern. Psilocybin was obtained from the BAG (DPN), Bern, and prepared as capsules (1 and 5 mg) at the Pharmaceutical Institute of the University of Bern, Switzerland.

Twenty-five healthy volunteers were recruited from university staff and screened by psychiatric interview to assure that they had neither personal nor family histories of major psychiatric disorders in first-degree relatives. Subjects with a history of illicit drug abuse were excluded from the study. Subjects were healthy according to physical examination, electrocardiogram, and blood analyses. All subjects gave written informed consent. The psilocybin dose used was high enough (0.25 mg/kg, p.o.) to induce robust psychological alterations over a period of 120-180 min.[3] The doses of haloperidol (0.021 mg/kg, i.v.) and risperidone (1 mg, p.o.) chosen were expected to occupy about 55-65% of dopamine D2 receptors.[21,22]

Experiment 1

Fifteen subjects (eight male, seven female; mean age (± s.d.) 29.7 ± 5.3) were divided into three groups of five and tested at monthly intervals. Subjects in the ketanserin pretreatment experiment received pretreatment with either placebo, 20 mg ketanserin, or 40 mg ketanserin (p.o.); subjects in the haloperidol pretreatment experiment received either placebo, or 0.021 mg haloperidol (i.v.). 75 min later. Subjects of both groups received treatment with either placebo or 0.25 mg/kg psilocybin (p.o.). Subjects in the risperidone pretreatment experiment received pretreatment with either placebo, 0.5 mg risperidone, or 1.0 mg risperidone (p.o.). In these subjects, placebo or 0.25 mg/kg psilocybin (p.o.) was administered 90 min after pretreatment, due to kinetic reasons of risperidone. The (APZ-OAV) rating scale and a delayed response task (DRT) were applied just prior to treatment with either placebo or psilocybin and again 80 min after to coincidence with the peak effects of psilocybin.[9]

Experiment 2

A second group (five male, five female; age 28.4 ± 4.0) received pretreatment with either placebo or 40 mg ketanserin (p.o.). After 75 min subjects received treatment with either placebo or 0.25 mg/kg psilocybin (p.o.). APZ-OAV ratings (but no DRT) were performed according to the protocol of experiment 1.

The Altered State of Consciousness (APZ-OAV) rating scale yields three dimensions (factors) comprised of several item clusters.[19] The first subscale, OSE (oceanic boundlessness), measures derealization and depersonalization phenomena associated with a positive basic mood ranging from heightened feelings to sublime happiness, grandiosity, and alterations in the sense of time and space. The second subscale, VUS (visionary restructuralization), assesses illusions, (pseudo-) hallucinations, synaesthetic phenomena, and changes in the meaning of various percepts. The third subscale AIA (dread of ego-dissolution), measures thought disorder, anxious ego-disintegration, loss of control over body and thought, and derealization phenomena associated with arousal and anxiety.

To assess working memory deficits, a visual-manual delayed response task (DRT) was used, as previously reported in detail by Park *et al*.[20] and summarized here. In this DRT, subjects were required to respond to visually presented targets (black circles) by touching a position on a computer screen (a touch screen) with their hand. While subjects sat still on an armchair and stared fixedly at the center of the screen, a target appeared on the screen for 200 ms in one of eight possible locations on the circumference of an imaginary circle. After the presentation of each target, there was a 10 s delay period during which the subject had to perform a category shift task by reading changing numbers appearing in the center of the screen. After that the fixation point and eight reference circles (empty instead of black) appeared on the screen and subjects were required to touch the screen at the remembered position. If the correct target position was hit, the screen cleared and the next trial could begin. If the target position was incorrect, the reference circles remained on the screen until the subjects found the correct position or until 10 s had elapsed, whichever was sooner. There were 32 randomized trials, four at each location. Response times in milliseconds of correct trials were recorded.

The data for each APZ-OAV scale and data for performance on the DRT (response times) were analyzed separately for each antagonist with a two-way ANOVA (analysis of variance) with pretreatment (placebo and dose of antagonist) and drug (placebo and psilocybin) as within-subjects factors. When significant main effects or interactions were revealed in the ANOVA, Tukey post hoc comparisons were done. The significance level of the main factors and/or interactions are cited in the text, and those for Tukey's post hoc tests of individual groups are shown in the figures. Since haloperidol appeared to increase the psilocybin-induced AIA scores and the reaction time on the DRT, but no significant interactions were found in the two-way ANOVAs, the significance of these increases was also tested using non-parametric Friedman ANOVA. The Spearman correlation coefficient was used to evaluate correlations between changes in reaction time of DRT task and psycho(patho)logical alterations. The criterion for significance was set at $p < 0.05$.

Results

Psilocybin (0.25 mg/kg, p.o.) produced a psychotic syndrome including changes in mood, disturbances of sensory perception and thought processes, and impaired ego-functioning. The drug effects began 20-30 min after administration, peaked after another 30-50 min, and lasted 1-2 h. Thus psychological measurements and neuropsychological testing were undertaken during the peak drug effects.

The APZ-OAV scores for placebo, psilocybin, and psilocybin plus the different doses of antagonists for experiment 1 are summarized in Fig. 1. Two-way ANOVA's and Tukey's *post hoc* comparisons revealed that psilocybin significantly increased the OSE, VUS and AIA scores in the ketanserin, risperidone and haloperidol groups (Fig. 1). The increase in the OSE score was due to a prominent increase in derealization associated with euphoria, exaltation or grandiosity, and an altered sense of time and space. The increase in the VUS score was attributable to perceptual alterations including visual disturbances ranging from illusions to complex scenery hallucinations, synaesthesias, and changed meaning of percepts. The increase in AIA scores was mainly due to an anxiously experienced loss of ego-boundaries, thought disorder, and moderate suspiciousness and paranoid ideation.

As shown in Fig. 1, pretreatment with the 5-HT_2 antagonist ketanserin dose-dependently blocked psilocybin-induced psychosis, as revealed by two-way ANOVAs and significant drug x pretreatment interactions (OSE (F(2,8) = 12.2, $p < 0.004$); VUS (F(2,8) = 26.3, $p < 0.0003$); AIA (F(2,8) = 21.7, $p < 0.0006$)). Specifically, 20 mg ketanserin reduced the psilocybin-induced APZ-OAV scores by about 50-70%, while 40 mg ketanserin completely prevented the development of psilocybin effects in four of five subjects (98-100%). In the remaining subject, the mean APZ-OAV scores were also markedly reduced (75-87%), but the subject still reported discrete distortions in the experience of time and space, and impaired body control. Similarly, 0.5 mg of the mixed 5-$HT_{2/D2}$ antagonist risperidone attenuated the effects of psilocybin on all three APZ-OAV scales (69-78%), while 1 mg risperidone effectively blocked the development of psilocybin-induced psychosis (98-99%). Two-way ANOVAs yielded again significant drug x pretreatment interactions (OSE (F(2,8) = 7.4, $p < 0.02$); VUS (F(2,8) = 8.2, $p < 0.01$); AIA (F(2,8) = 8.5, $p < 0.01$)). By themselves, neither ketanserin nor risperidone (0.5 and 1.0 mg) had any effects on any APZ-OAV scores.

In contrast, pretreatment with haloperidol (0.021 mg/kg, i.v.) reduced the effect of psilocybin only on the OSE scale (54% reduction; drug x pretreatment interaction for OSE (F(1,4) = 20.4, $p < 0.01$). Tukey's *post hoc* analysis revealed that this reduction was significant (Fig. 1). Haloperidol had no influence on psilocybin-induced visual illusions and hallucinations as measured by the VUS scale (main effect of drug (F(1,4) = 52.3, $p < 0.002$)) and pretreatment (F(1,4) = 0.51, $p < 0.5$), and drug x pretreatment interaction (F(1,4) = 0.4, $p < 0.5$)). Surprisingly, haloperidol uniformly increased the AIA scores in all of the subjects treated with psilocybin (148% increase). A two-way ANOVA revealed significant main effect of drug (F(1,4) = 14.4, $p < 0.02$) and pretreatment (F(1,4) = 8.7, $p < 0.04$), but no significant drug x pretreatment interaction (F(1,4) = 2.1, $p < 0.22$). Additional non-parametric Friedman ANOVAs showed that this psilocybin-induced increase in AIA scores after haloperidol was significantly greater than psilocybin alone ($p < 0.025$) and that haloperidol by itself slightly (9.6%), but not significantly, increased the AIA scores as compared to placebo. Furthermore, item-based analysis of the AIA scores revealed that psilocybin mainly increased thought disorder and anxiety after pretreatment with haloperidol.

As seen in Figure 2, psilocybin also increased the reaction time on the memory-guided delayed response task during the peak effects of the drug. Again, ketanserin and risperidone, but not haloperidol, dose-dependently blocked the increase in reaction time on the DRT, as revealed by significant drug x pretreatment interactions (ketanserin (F(2.8) = 6.0, $p < 0.03$); risperidone (F(2.8) = 4.8, $p < 0.04$)). Additional Friedman ANOVAs showed that ketanserin, risperidone and haloperidol by themselves did not have any significant effects on reaction times. Performance as measured by the rate of correct responses did not differ significantly between the various conditions. Interestingly, the impairment in reaction time did not correlate significantly with changes in the APZ-OAV scores.

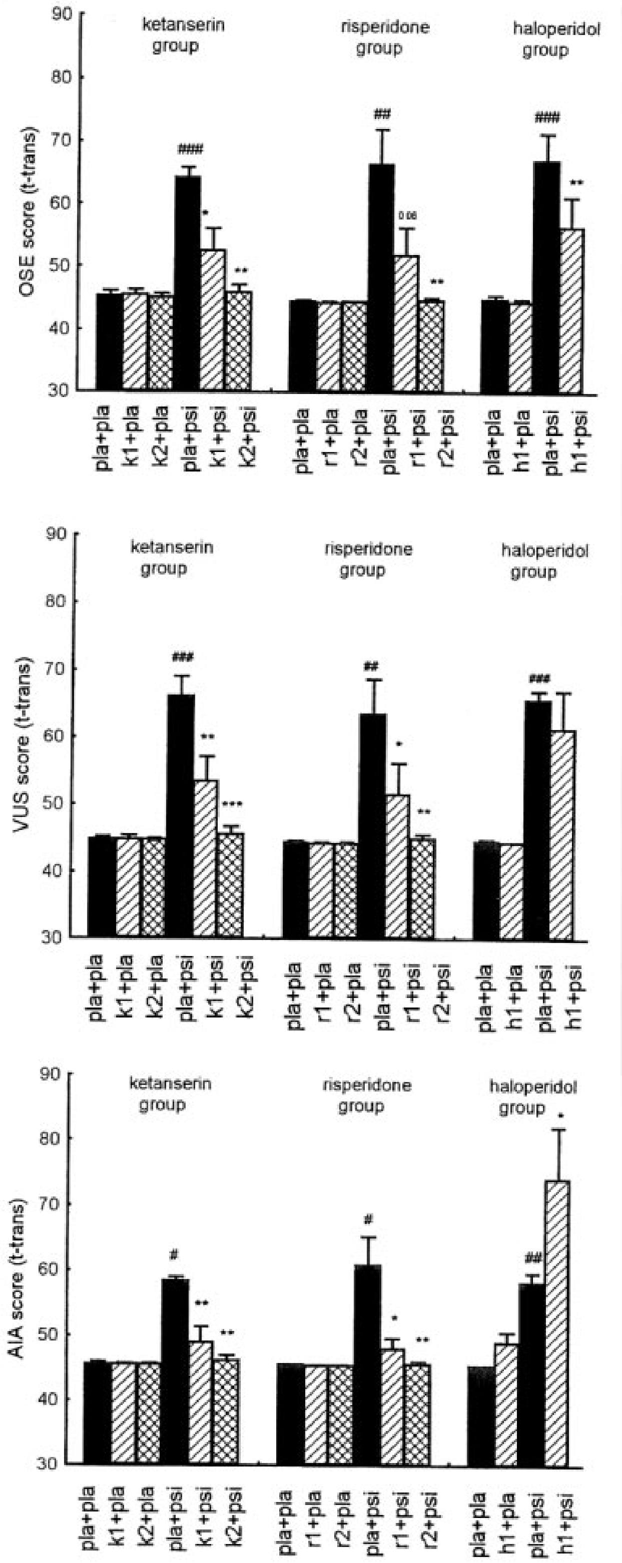

FIG. 1. Bars show the pretreatment alone effects of placebo, ketanserin, risperidone and haloperidol, and the effects of pretreatment on the psilocybin-induced APZ-OAV scores (OSE, VUS and AIA) in normal subjects. The OSE scale includes items for derealization and depersonalization associated with euphoria, the VUS scale rates illusions, hallucinations, and changed meaning, and the AIA scale rates anxious ego-dissolution, thought disorder, and paranoia. Data are means ± s.e. ($n = 5$ for each antagonist): placebo (pla), psilocybin (psi = 0.25 mg/kg), ketanserin (k1 = 20 mg, k2 = 40 mg, p.o.), risperidone (r1 = 0.5 mg, r2 = 1.0 mg, p.o.) and haloperidol (h1 = 0.021 mg/kg, i.v.). Significant increases from placebo to psilocybin: #$p < 0.05$, ##$p < 0.01$, ###$p < 0.001$. Significant decreases from psilocybin to antagonist conditions: *$p < 0.05$, **$p < 0.01$ (Tukey's *post hoc* test). Note: The psilocybin-induced increase in AIA after haloperidol was tested by a Friedman ANOVA.

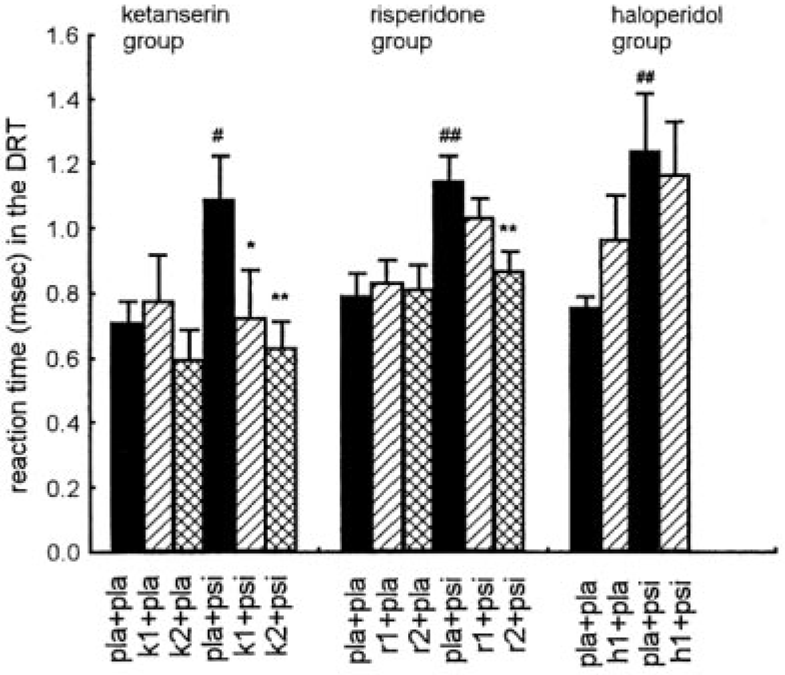

FIG. 2. Bars show the pretreatment alone effects of placebo, ketanserin, risperidone, and haloperidol and the effects of pretreatment on the psilocybin-induced spatial working memory deficits as measured by a memory-guided delayed response task (DRT). Data are means ± s.e. ($n = 5$ for each antagonist). For abbreviations see Fig. 1. Significant increases in reaction time (rt) from placebo to psilocybin: #$p < 0.05$, ##$p < 0.01$. Significant decreases from psilocybin to antagonist conditions: *$p < 0.05$, **$p < 0.01$ (Tukey's *post hoc* test). Note: The psilocybin-induced increase in reaction time after haloperidol was tested by a Friedman ANOVA.

Given the importance of the ketanserin findings obtained in experiment 1, a second group of 10 subjects was tested to corroborate the results obtained with 40 mg ketanserin. Once again, pretreatment with 40 mg ketanserin effectively blocked the effects of psilocybin on all APZ-OAV measures by 87-96%. Two-way ANOVAs yielded significant drug x pretreatment interactions for OSE ($F(1.9) = 51.7$, $p < 0.0001$), VUS ($F(1.9) = 111.7$, $p < 0.00001$), and AIA ($F(1.9) = 16.2$, $p < 0.003$) and Tukey's *post hoc* comparisons confirmed that these effects were significant (Fig. 3).

Discussion

The present results provide compelling evidence that the model psychosis induced by psilocybin in healthy human volunteers is the result of a specific activation of the 5-HT$_2$ subtype of serotonin receptors. These findings validate the many studies in animals indicating that the behavioral effects of hallucinogens are attributable to 5-HT$_2$ agonist actions.

This study corroborates the several previous suggestions of similarities between the early and acute stages of schizophrenia and the psychological effects of indoleamine-derived hallucinogens such as psilocybin and LSD.[3,5,7] In particular, the finding that psilocybin produced derealization and depersonalization associated with heightened mood, euphoria and/or grandiosity (OSE) and visual hallucinations (VUS) is consistent with the observation that the earliest affective changes in incipient schizophrenia are often pleasurable and that visual, as opposed to auditory, hallucinations occur with higher prevalence in first-break than chronic schizophrenics[7]. Anxious ego-dissolution, loss of body and thought control, and ideas of reference (AIA), however, are not only common features of both psilocybin-induced psychosis and early schizophrenic stages, but also occur in chronic schizophrenics in acute episodes. Indeed, a recent study demonstrated that schizophrenics during both first episodes and relapse had similar prominent OSE and AIA scores as seen in this study in psilocybin subjects.[1] The most novel aspect of the present findings is the demonstration that psilocybin-induced psychosis could be completely prevented by either the atypical neuroleptic and mixed 5-HT$_{2/D2}$ antagonist risperidone or by the 5-HT$_2$ antagonist ketanserin, but not by the typical neuroleptic and D2 antagonist haloperidol. This finding adds substantial evidence to the view that 5-HT$_2$ agonism is responsible for the psychological effects of psilocybin and, presumably, other indoleamine hallucinogens. Furthermore, the finding that ketanserin, with about 100-fold greater potency at the 5-HT_{2A} vs 5-HT_{2C} receptor, completely blocked psilocybin-induced psychosis strongly indicates that the effects of psilocybin are mediated by 5-HT_{2A} rather than 5-HT_{2C} receptor activation. This interpretation is corroborated by recent findings demonstrating that the highly selective 5-HT_{2A} receptor antagonist M100,907 (formerly MDL 100,907), but not 5-HT_{2C} antagonists, completely antagonized the disruptive effect of the hallucinogenic 5-$HT_{2A/C}$ agonist DOI on prepulse inhibition (PPI) of startle in rats.[14] Insofar that PPI deficits and 5-HT_{2A} receptor alterations were recently found in schizophrenic patients,[23] the present data are consistent with the hypothesis that serotonergic hyperactivity may also contribute to the pathophysiology of schizophrenia.

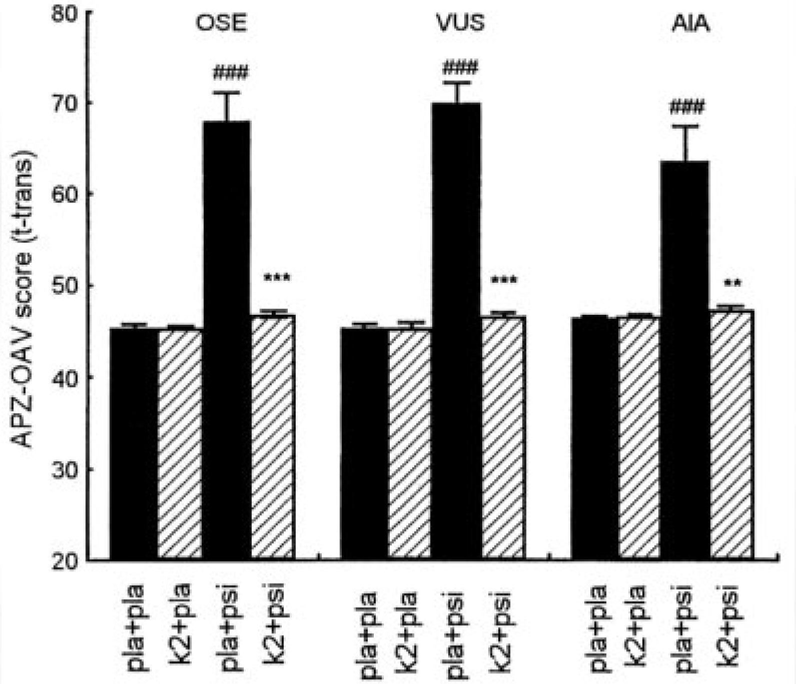

FIG. 3. A second experiment to corroborate the effects of placebo and ketanserin pretreatment on the psilocybin-induced APZ-OAV scores was performed in normal subjects. Data are means ± s.e. (n = 10): placebo (pla), ketanserin (k2 = 40 mg, p.o.) and psilocybin (psi = 0.25 mg/kg). Significant increases from placebo to psilocybin: ###$p < 0.001$. Significant decreases from psilocybin to antagonist conditions: **$p < 0.01$, ***$p < 0.001$ (Tukey's *post hoc* test).

To the extent that the effects of psilocybin studied here are relevant to the symptoms of acute schizophrenia, the blockade of these effects by a 5-HT_2 antagonist supports the notion that 5-HT_2 antagonism may contribute significantly to the antipsychotic actions of atypical neuroleptics.[18] In this regard, it is particularly interesting to note that the typical antipsychotic haloperidol was substantially less effective than risperidone in blocking the psychosis-like symptoms produced by psilocybin, despite the fact that the doses of haloperidol and risperidone were selected to have comparable effects on dopamine D2 receptors.[21,22] In contrast, haloperidol even increased psilocybin-induced AIA scores. This finding might be somewhat surprising, but is consistent with single case reports indicating that classic neuroleptics do enhance, rather than ameliorate, LSD-induced psychosis.[24] Whether psilocybin increases the AIA scores after pretreatment with haloperidol through a serotonergic modulation of dopamine or other neurotransmitter systems, such as GABA,[10] or both, cannot be inferred from the present data. Nevertheless, despite the fact that psilocybin and psilocin do not act directly upon D2 receptors[16] haloperidol partially ameliorated psilocybin- induced OSE scores. This finding could indicate that psilocybin has an indirect influence on dopaminergic systems which is then antagonized by haloperidol. Finally, haloperidol, in contrast to ketanserin and risperidone, had no effects on psilocybin-induced perceptual disturbances and hallucinatory phenomena (VUS) indicating that these symptoms are specifically attributable to direct activation of 5-HT_{2A} receptors and do not depend upon the dopaminergic system.

The second important result was that psilocybin produced spatial working memory deficits comparable to those seen in schizophrenic patients[20] and that these deficits could be completely prevented by 5-HT_2, but not D2 antagonism. This finding strongly suggests that 5-HT, and particularly 5-HT_{2A} receptor stimulation, may also contribute to cognitive impairments in schizophrenia. This interpretation is consistent with the observation that schizophrenic patients with cognitive deficits respond better to atypical than typical neuroleptics.[25] Furthermore, the observation that psilocybin-induced working memory deficits did not correlate with psychopathological measures is in line with the notion that cognitive deficits in schizophrenia appear to occur independent of positive and negative symptoms of schizophrenia.[25]

Conclusion

The present study demonstrated that psilocybin produces schizophrenia-like symptoms primarily through 5-HT_2 receptor stimulation. This finding adds further evidence to the hypothesis that excessive 5-HT_2 receptor activation, particularly 5-HT_{2A}, may be a critical factor in psychotic symptom formation and cognitive deficits in schizophrenia, at least in a subset of schizophrenic patients.[23] Thus, selective 5-HT_{2A} antagonists may be useful in normalizing such imbalances.[18] Furthermore, the classic amphetamine-induced model of psychosis has generally been used to assess the actions of typical antipsychotics, such as haloperidol, whose efficacy appears to be attributable to dopamine antagonism. By contrast, it appears that the psilocybin-induced psychosis may offer a potential model to study specifically those aspects of atypical antipsychotic action that differ from the actions of typical antipsychotics.

Psychedelic drugs have a long history of use in healing ceremonies, but despite renewed interest in their therapeutic potential, we continue to know very little about how they work in the brain. Here we used psilocybin, a classic psychedelic found in magic mushrooms, and a task-free functional MRI (fMRI) protocol designed to capture the transition from normal waking consciousness to the psychedelic state. Arterial spin labeling perfusion and blood-oxygen level dependent (BOLD) fMRI were used to map cerebral blood flow and changes in venous oxygenation before and after intravenous infusions of placebo and psilocybin. Fifteen healthy volunteers were scanned with arterial spin labeling and a separate 15 with BOLD. As predicted, profound changes in consciousness were observed after psilocybin, but surprisingly, only decreases in cerebral blood flow and BOLD signal were seen, and these were maximal in hub regions, such as the thalamus and anterior and posterior cingulate cortex (ACC and PCC). Decreased activity in the ACC/medial prefrontal cortex (mPFC) was a consistent finding and the magnitude of this decrease predicted the intensity of the subjective effects. Based on these results, a seed-based pharmaco-physiological interaction/ functional connectivity analysis was performed using a medial prefrontal seed. Psilocybin caused a significant decrease in the positive coupling between the mPFC and PCC. These results strongly imply that the subjective effects of psychedelic drugs are caused by decreased activity and connectivity in the brain's key connector hubs, enabling a state of unconstrained cognition.

Keywords: default mode network, hallucinogens, serotonin, depression, 5-HT$_{2A}$ receptor.

Psilocybin is the prodrug of psilocin 4-hydroxy-dimethyltryptamine), the primary hallucinogenic component of magic mushrooms, and a classic psychedelic ("mind-manifesting") drug. Psilocybin has been used for centuries in healing ceremonies[1] and more recently in psychotherapy[2]; it is capable of stimulating profound existential experiences[3], which can leave a lasting psychological impression[4]. However, despite a wealth of literature on its phenomenology, we currently know very little about how its effects are produced in the brain. The present study sought to address this question using complementary functional MRI (fMRI) techniques and a protocol designed to image the transition from normal waking consciousness to the psychedelic state. Two groups of healthy subjects were scanned using arterial spin labeling (ASL) perfusion and blood-oxygen level-dependent (BOLD) fMRI during intravenous infusion of psilocybin. Infused over 60 s 2 mg in 10-mL saline), psilocybin's subjective effects begin within seconds[5], allowing the capture of the corresponding change in brain state.

Results

ASL Perfusion fMRI

Fifteen healthy, hallucinogen-experienced subjects (five females), mean age 34.1 (SD 8.2) were scanned with ASL. Subjects underwent an anatomical scan followed by two task-free functional scans, each lasting 18 min. Subjects were instructed to relax and a fixation cross was displayed. Solutions were infused manually over 60 s, beginning 6 min after the start of each functional scan. Subjects received placebo (10-mL saline) in the first scan and psilocybin (2 mg in 10-mL saline) in the second. The intensity of the subjective effects was rated via button press on a 0-10 visual analog scale (10 = extremely intense effects) at the start of each functional scan, just before infusion, 5-min postinfusion, and 12-min postinfusion. The average rating 5-min postinfusion was 6.7 (±1.9), and 5.2 (±2.3) 12-min postinfusion. Earlier work showed that the effects of 2 mg i.v. psilocybin are comparable with ~15 mg of orally administered psilocybin, which is considered a moderate dose [6]. Nineteen additional items were rated immediately after each ASL scan. Fig. 1 displays the top 10 rated items from the two studies. Ratings for all of the items used in the ASL and BOLD studies can be found in Table S1.

The interaction between cerebral blood flow (CBF) and the infusion event was modeled, contrasting CBF before and after infusion. The subjective effects began toward the end of the infusion period and reached a sustained peak after ~4 min [5]. The first level results were entered into a higher level analysis, contrasting CBF after psilocybin with CBF after placebo for all 15 subjects. Fig. 2 displays these results.

Table S1. All items rated after each scan.

Item	ASL plac	ASL psilo	BOLD plac	BOLD psilo	Combine: psilo - plac (SD)
I saw geometric patterns			0.3	73.5	73.2 (16.9)
I saw my surroundings change in unusual ways	7.1	75.3			68.2 (21.3)
I felt unusual bodily sensations			6.5	67.3	60.9 (23.1)
Things looked strange	8.1	69.9	2.2	59.3	59.5 (22)
My sense of size or space was altered	3.9	64.1	0.9	53.0	56.2 (23.2)
Sounds influenced things I saw			2.4	57.5	55.1 (21.7)
My imagination was extremely vivid	3.5	54.7	6.5	64.7	54.7 (23.9)
My perception of time was distorted			5.2	58.2	53 (20.2)
My sense of size or space was distorted			0.9	53.0	52.1 (16.3)
My sense of time was altered	6.3	55.4	5.2	58.2	51 (24.3)
The experience had a dreamlike quality	8.9	53.3	6.2	57.5	47.8 (24.2)
It felt like I was floating			3.7	51.1	47.5 (23.9)
My thoughts wandered freely	11.0	57.7	10.5	56.7	46.4 (23.2)
Everything seemed 'alive'	1.5	47.1			45.5 (21.6)
It felt like I was merging with my environment			2.2	47.3	45.1 (21.9)
I felt a sense of awe	3.1	48.0			44.9 (21.5)
The experience had a supernatural quality			0.7	44.5	43.7 (20.2)
I experienced a loss of separation from my surroundings			2.1	45.3	43.2 (18.7)
I felt a sense of joy	5.1	45.9			40.8 (25.4)
My sense of self was altered	2.6	43.3			40.7 (23.4)
The experience had a spiritual or mystical quality			1.8	40.3	38.5 (23.6)
My thinking was muddled	5.9	40.9	1.4	41.5	37.5 (19)
I felt a profound inner peace			7.0	41.3	34.3 (21.2)
I lost all sense of ego			3.2	34.6	31.4 (20.6)
The experience had a mystical quality	1.9	31.5			29.5 (19.6)
The experience had a magical or supernatural quality	2.4	31.7			29.2 (20.2)
The experience had a spiritual quality	2.7	28.2			25.5 (19)
I thought about myself and my past	4.8	22.9			18.1 (17)
I feared losing control of my mind	3.3	18.0	3.1	14.6	13.1 (16.7)
I felt afraid	5.8	13.7	6.5	20.4	10.9 (17.3)
I felt suspicious or paranoid	4.1	6.0	3.5	14.3	6.3 (12.8)

All of these items were rated at the end of each scan in a visual analog scale format with a bottom anchor of "no more than usually" and a top anchor of "much more than usually." Scores are expressed as a percentage, with 100% being a mark adjacent to the top anchor "much more than usually." All items were rated significantly higher after psilocybin than placebo with the exception of "I felt afraid" and "I felt suspicious or paranoid" (t tests, P=0.05).

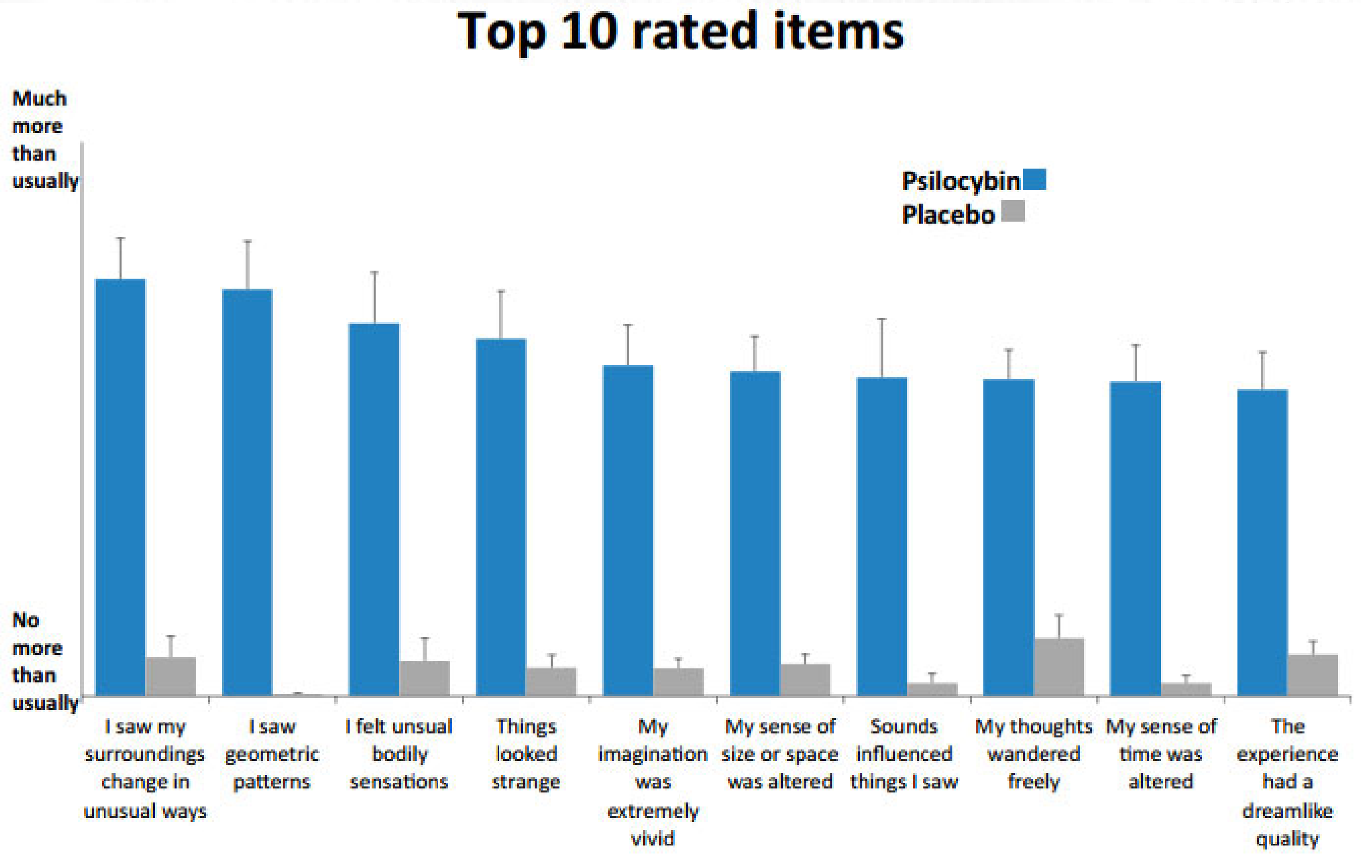

Fig. 1. Subjective ratings ($n = 30$). Displayed are mean values + SEs. Ratings were given shortly after the scans. Subjects were instructed that "no more than usually" refers to normal waking consciousness. All 10 items were scored significantly higher after psilocybin than placebo ($P < 0.01$).

The group level results (Fig. 2) revealed significant CBF decreases in subcortical (bilateral thalamus, putamen, and hypothalamus) and cortical regions [the posterior cingulate cortex (PCC), retrosplenial cortex, precuneus, bilateral angular gyrus, supramarginal gyrus, rostral and dorsal anterior cingulate cortex (ACC), paracingulate gyrus, medial prefrontal cortex (mPFC), frontoinsular cortex, lateral orbitofrontal cortex, frontal operculum, precentral gyrus, and superior, middle and inferior frontal gyrus] (Fig. S1). The decreases were localized to high-level association regions (e.g., the PCC and mPFC) and important connector hubs, such as the thalamus, PCC and ACC/mPFC.

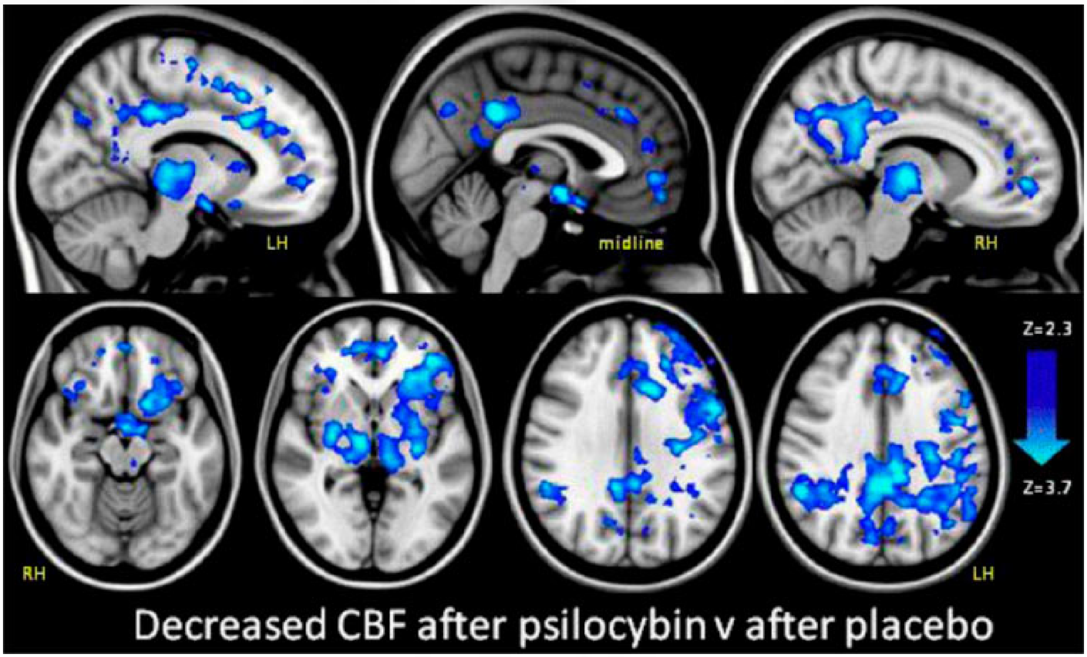

Fig. 2. Decreased CBF after psilocybin (ASL perfusion fMRI). Regions where there was significantly decreased CBF after psilocybin versus after placebo are shown in blue (z: 2.3-3.7). Mixed effects analysis, $z > 2.3$, $P < 0.05$ whole-brain cluster-corrected, $n = 15$. LH, left hemisphere; RH, right hemisphere. Note, we observed no increases in CBF in any region.

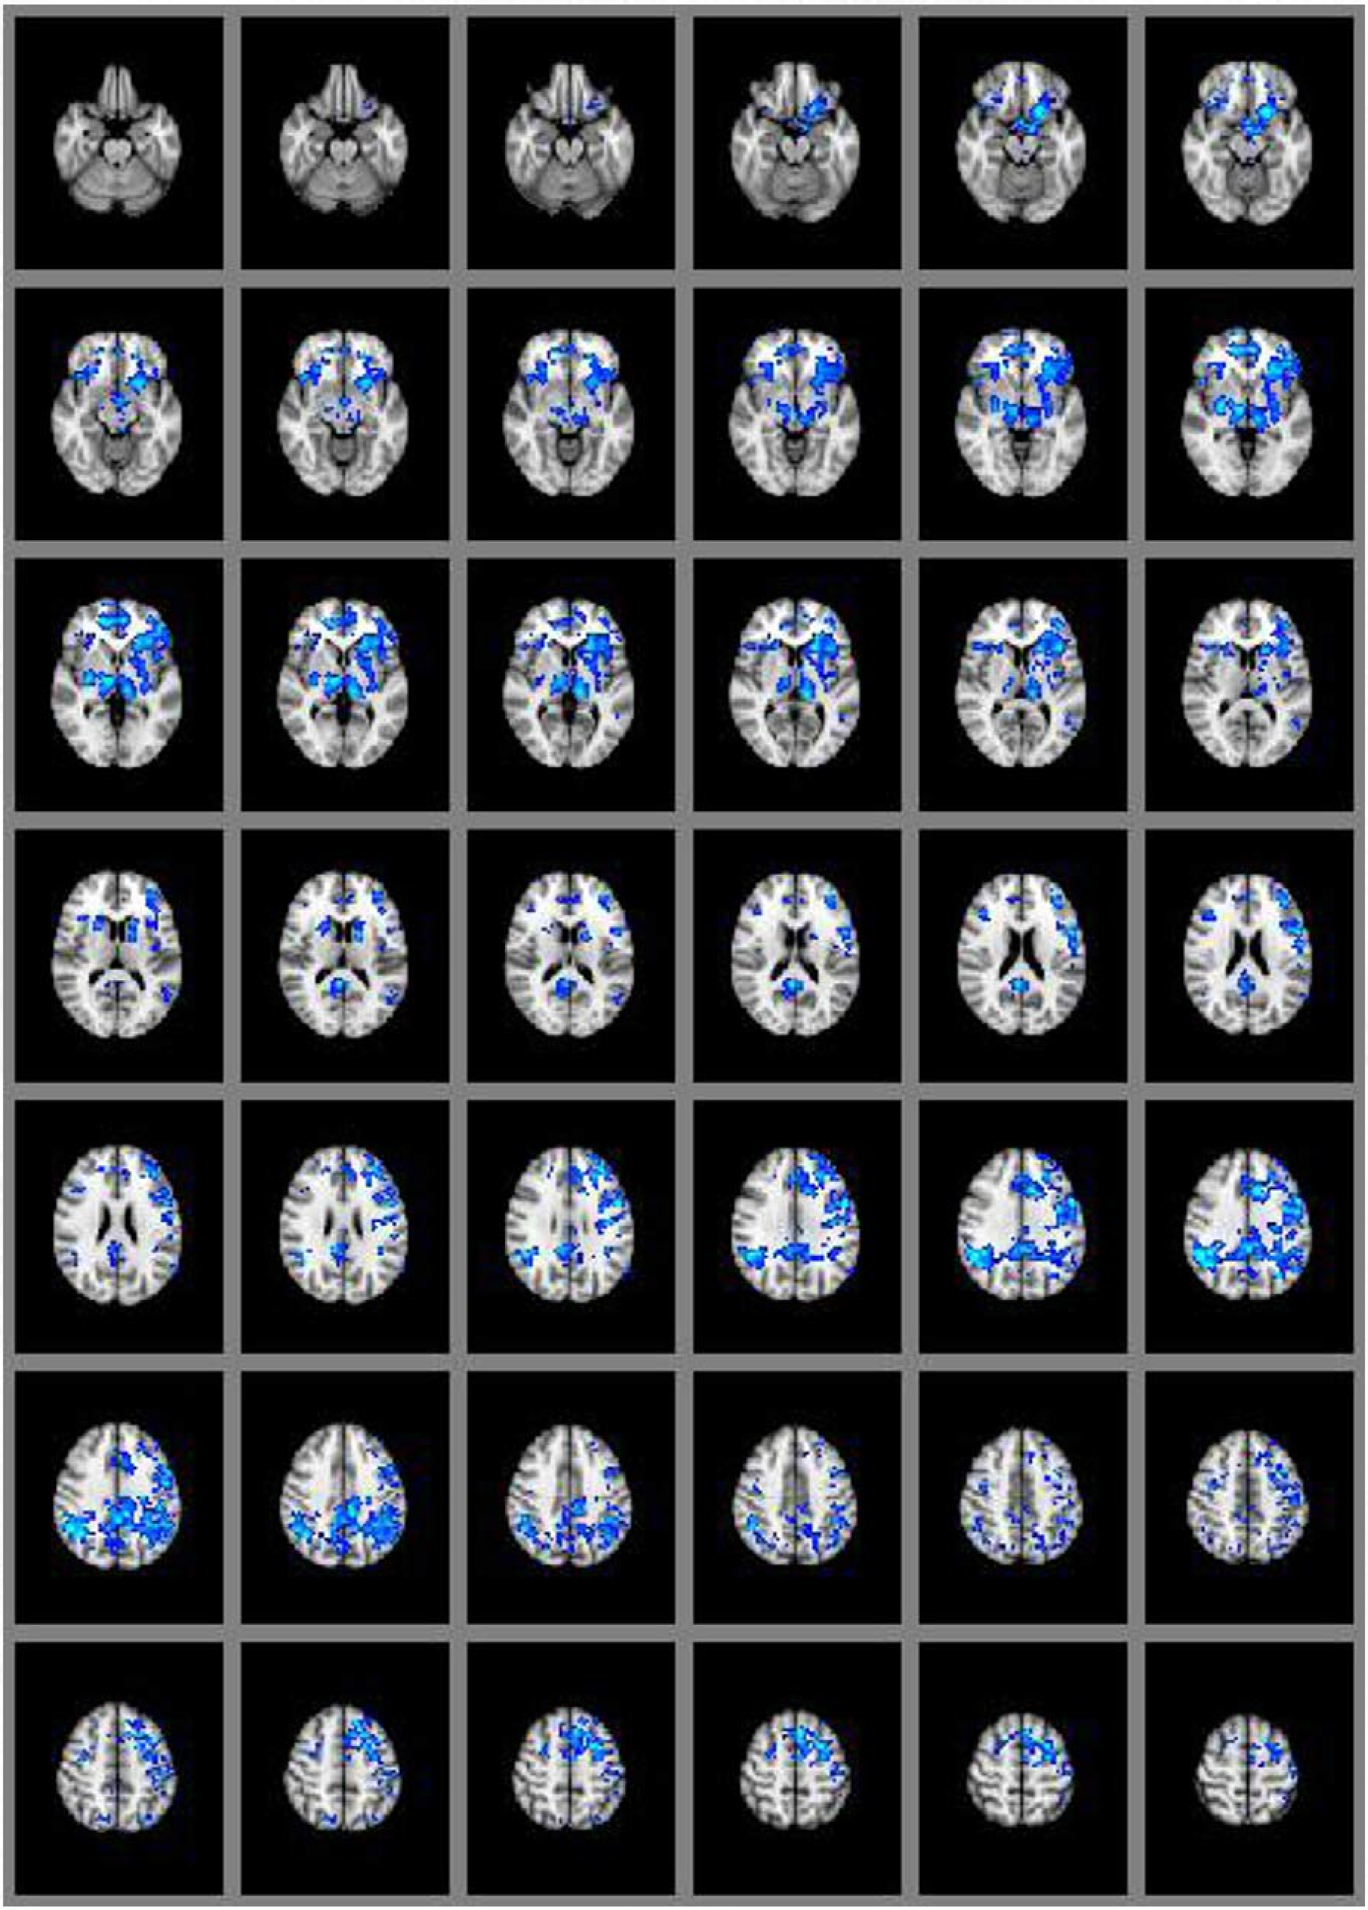

Fig. S1. Slices for arterial spin labeling (ASL) result. Lightbox display of slices showing regions where there were significant decreases in cerebral blood flow (CBF) after psilocybin versus placebo. Mixed-effects analysis, cluster threshold = 2.3, $P = 0.05$ whole-brain corrected, $n = 15$. The right hemisphere is shown on the left.

To assess the temporal dynamics of the CBF changes post-infusion, thalamic, ACC, and PCC masks were made; voxels within these were restricted to those that were significantly decreased after psilocybin. For each region of interest (ROI), the percent CBF change postinfusion was plotted against time (Fig. 3). All ROIs showed steep decreases in CBF after psilocybin that were sustained for the duration of the scan.

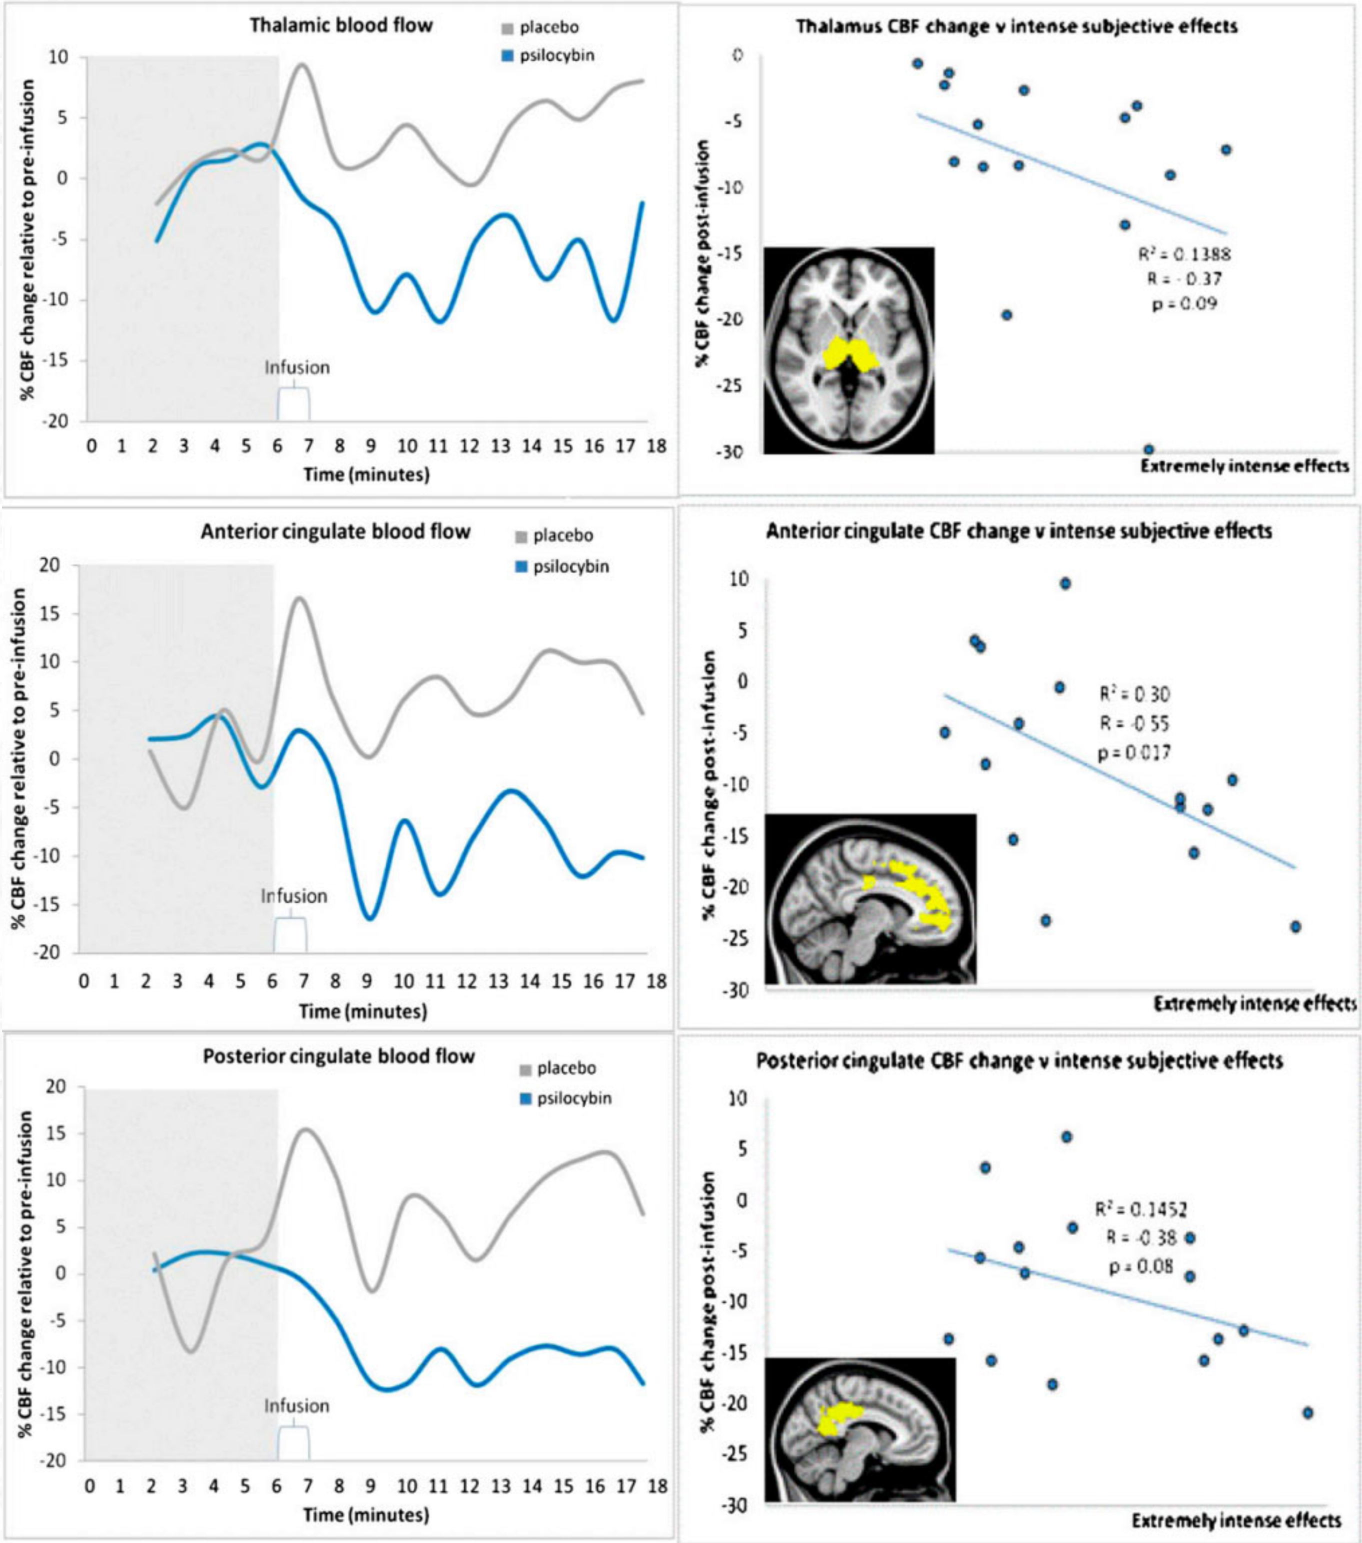

Fig. 3. Group CBF changes over time (*Left*) and CBF vs. subjective effects (*Right*). Plots on the left show blood flow changes over time for the thalamus, ACC, and PCC. These plots were made by calculating the postinfusion change in CBF as a percentage of the preinfusion CBF. This process was done for each ROI for each individual subject and then the group mean was plotted. Note, these plots are shown for display purposes; error bars are not included because the inclusion of error is implicit in the statistical parametric maps shown in Fig. 2. Plots on the right show the relationship between ROI CBF changes after psilocybin-infusion for each subject and their ratings of the intensity of the subjective effects given 5- and 12-min postinfusion (plotted are the average of these two ratings). There was a significant negative correlation between ACC CBF change postpsilocybin and intense subjective effects (Pearson's correlation, r = -0.55, P = 0.017, one-tailed) and CBF vs. intensity met a trend level significance for the thalamus and PCC ($P < 0.01$).

To test for a relationship between regional CBF changes and subjective effects, we plotted each subjects' ROI CBF change post-psilocybin against their ratings of drug effects intensity (Fig. 3D). For each ROI, it was evident that the greater the decreases in CBF, the more intense the subjective effects.

BOLD fMRI

A separate sample of 15 subjects was scanned with BOLD fMRI. The BOLD scans took place ~6 mo after the ASL. The sample included two females and had a mean age of 32 (SD 8.9). Subjects underwent an anatomical scan followed by an eyes-closed task-free BOLD scan, which lasted 12 min. This process occurred on two visits, ~14 d apart. Placebo was given on one occasion and psilocybin on the other in a balanced order. Infusions began 6 min after the start of the scan, following the same procedure as the ASL study. The data were high-pass filtered with a cutoff of 300 s and the pharmacodynamics of intravenous psilocybin was used to model changes in the BOLD signal coinciding with the infusion event [5]. The first level results were entered into a higher level analysis, contrasting BOLD signal changes before and after psilocybin, and before and after psilocybin versus before and after placebo (Fig. 4, Upper).

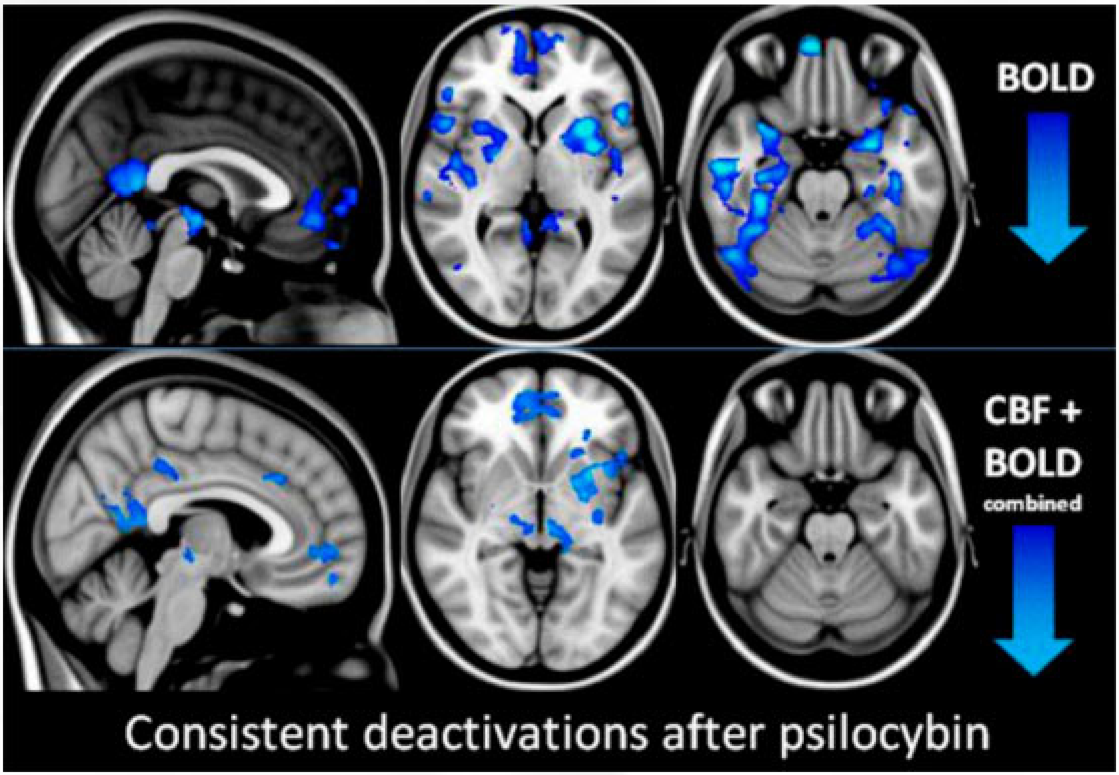

Fig. 4. Brain deactivations after psilocybin. (*Upper*) Regions where there was a significant decrease in the BOLD signal after psilocybin versus after placebo (z: 1.8-3). Mixed-effects analysis, $z > 1.8$, $P < 0.05$ whole brain cluster corrected, $n = 15$. (*Lower*) Regions where there was a consistent decrease in CBF and BOLD after psilocybin. For display purposes, significant BOLD decreases were calculated within a mask based on the ASL result (Fig. 2) at an uncorrected voxel level threshold of $P = 0.05$. Note, we observed no increases in CBF or BOLD signal in any region.

The regional decreases in BOLD signal were similar to the regional decreases in CBF observed with ASL, with consistent decreases in the mPFC, ventral PCC, putamen, and subthalamic nuclei (Fig. 4, Lower). There were, however, additional BOLD signal decreases (e.g., in higher order visual areas) that were not observed with ASL (Fig. 4, Upper, and Fig. S2).

Pharmaco-Physiological Interaction

These results implicate the ACC/mPFC in the mechanism of action of psilocybin. The ACC/mPFC showed decreased CBF (Fig. 2) and BOLD signal (Fig. 4) after psilocybin and the magnitude of CBF decreases correlated positively with the intensity of the drug's subjective effects (Fig. 3). Based on these results, a ventromedial prefrontal (vmPFC) ROI (Fig. 5, red) was chosen for a psycho-physiological interaction (PPI) analysis. PPIs test for changes in linear coupling under a psychological factor. In our case, this factor was the administration of psilocybin. This finding means that, strictly speaking, we are looking at a pharmaco-physiological interaction. Although commonly referred to as analyses of functional connectivity, PPIs can also be regarded as tests for changes in effective connectivity under a simple linear model of the influence of one region upon another.

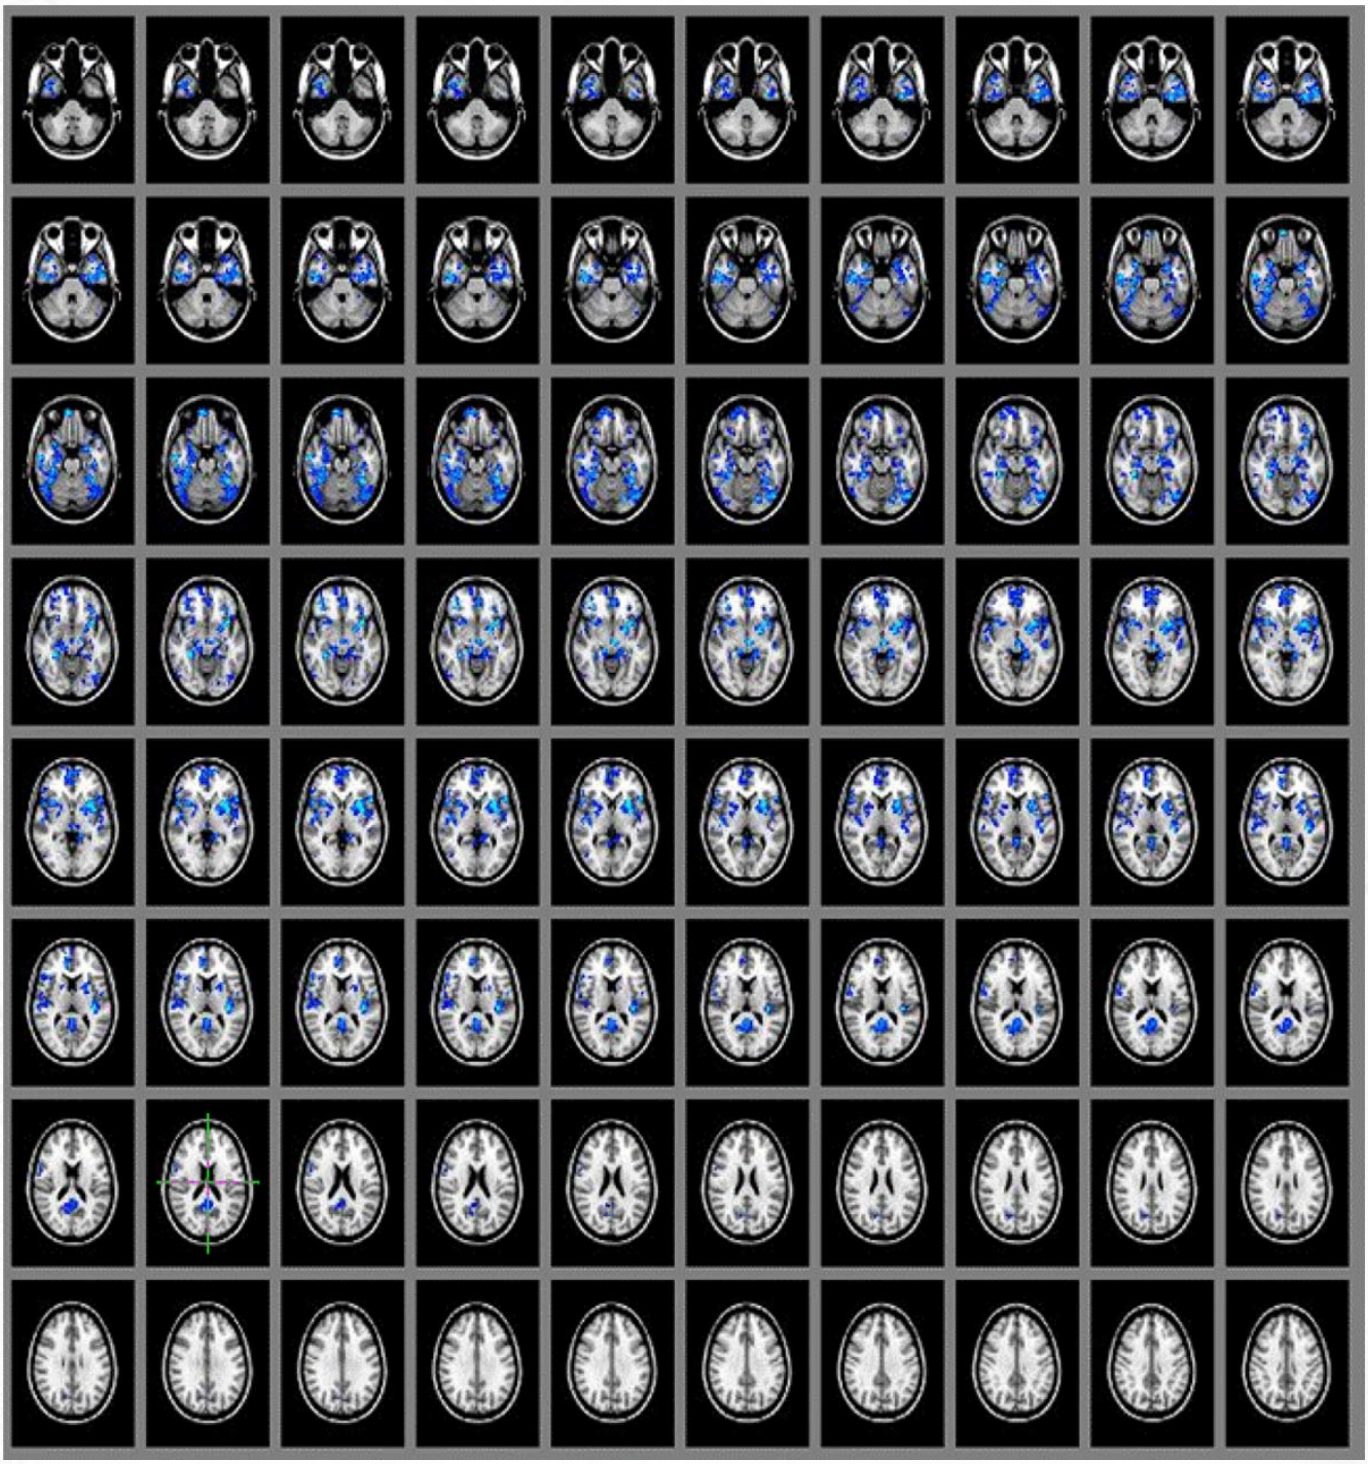

Fig. S2. Slices for blood-oxygen level-dependent (BOLD) result: Lightbox display of slices showing regions where there were significant decreases in BOLD after psilocybin vs. placebo. Mixed-effects analysis, cluster threshold = 1.8, $P < 0.05$ whole-brain corrected, $n = 15$. The right hemisphere is shown on the left.

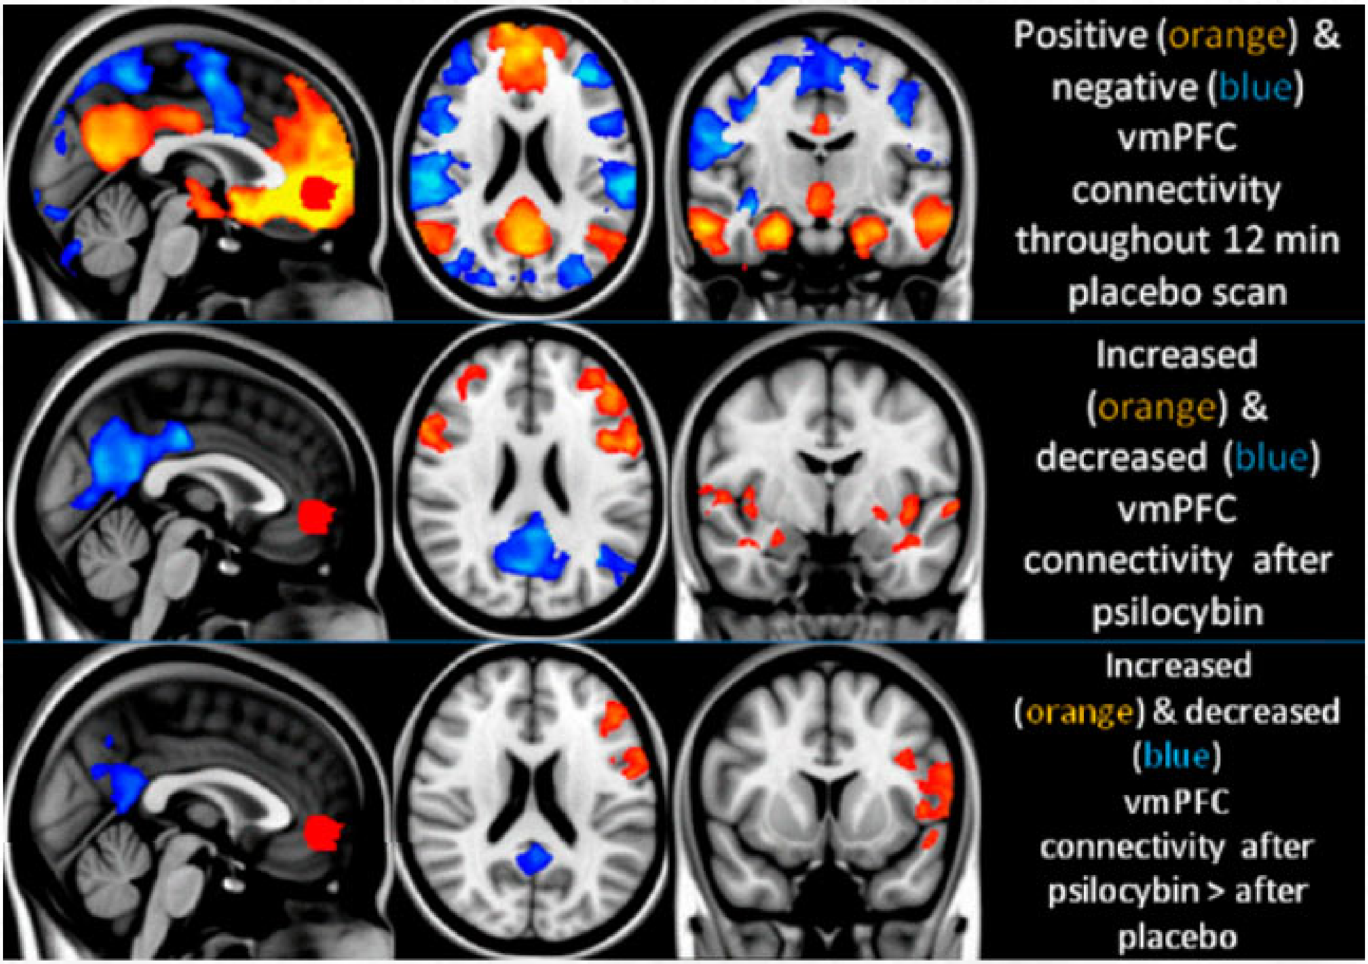
For each subject, the vmPFC time series was entered into a model that included independent gray matter, white matter, and cerebrospinal fluid time series as regressors of no-interest. Fig. 5 displays regions where activity was positively (yellow/orange) and negatively (blue) coupled to activity in the vmPFC throughout the placebo scan. However, the salient images are those shown as follows in Fig. 5: the middle row displays regions where activity became significantly less (blue) and more (red) coupled to activity in the vmPFC after psilocybin infusion and the bottom row displays these effects relative to those after placebo.



Positive (orange) & negative (blue) vmPFC connectivity throughout 12 min placebo scan
Increased (orange) & decreased (blue) vmPFC connectivity after psilocybin
Increased (orange) & decreased (blue) vmPFC connectivity after psilocybin > after placebo

Fig. 5. Psilocybin-induced changes in vmPFC (red) functional connectivity. (*Top*) Regions where activity was positively coupled to that of the vmPFC are shown in orange and regions where activity was "negatively" coupled to activity in the vmPFC are shown in blue (it should be noted however, that the appearance of negative connectivity is forced by regression of the global signal). (*Middle*) Significant increases (orange) and decreases (blue) in functional connectivity after psilocybin infusion. (*Bottom*) Increases and decreases in functional connectivity after psilocybin that were significantly greater than any connectivity changes after placebo. All analyses were mixed effects, $z > 2.3$, $P < 0.05$ whole-brain cluster corrected, $n = 15$. Note: The significant psycho-physiological interactions in the posterior PCC and left lateral parietal region suggest that the positive coupling (under placebo) has decreased significantly. This finding should not necessarily be interpreted as a negative coupling, simply a significant decrease in a positive coupling.

Physiological Correction and Breath-Hold

BOLD and ASL fMRI measure changes in a vascular signal that is coupled to changes in neural activity. It is therefore important to address factors that may modulate brain vasculature without affecting neural activity. For example, increases in blood carbon dioxide that occur with changes in respiration can drive increases in CBF [7]. Thus, to address the possibility that the effects observed in this study were driven by nonneural physiological changes, physiological variance (i.e., heart rate, respiration rate, and respiration depth) was regressed from the functional data before repeating the BOLD analyses described above. This correction step did not significantly alter the statistical parametric maps (Fig. S3), suggesting that changes in physiological parameters were not responsible for the positive outcomes.

Furthermore, to test the possibility that psilocybin had acted directly on the cerebral vasculature, we included a blocked breath-hold paradigm at the end of each BOLD scan. Hypercapnia is known to significantly increase the BOLD signal via CO_2-induced vasodilation (see ref. 7 and Fig. S4); thus, it was reasoned that a direct effect of psilocybin on brain vasculature would cause an altered BOLD response to breath-hold. However, no difference was found in the BOLD response to breath-hold under psilocybin and placebo, implying that the drug had not acted directly on the vascular system.

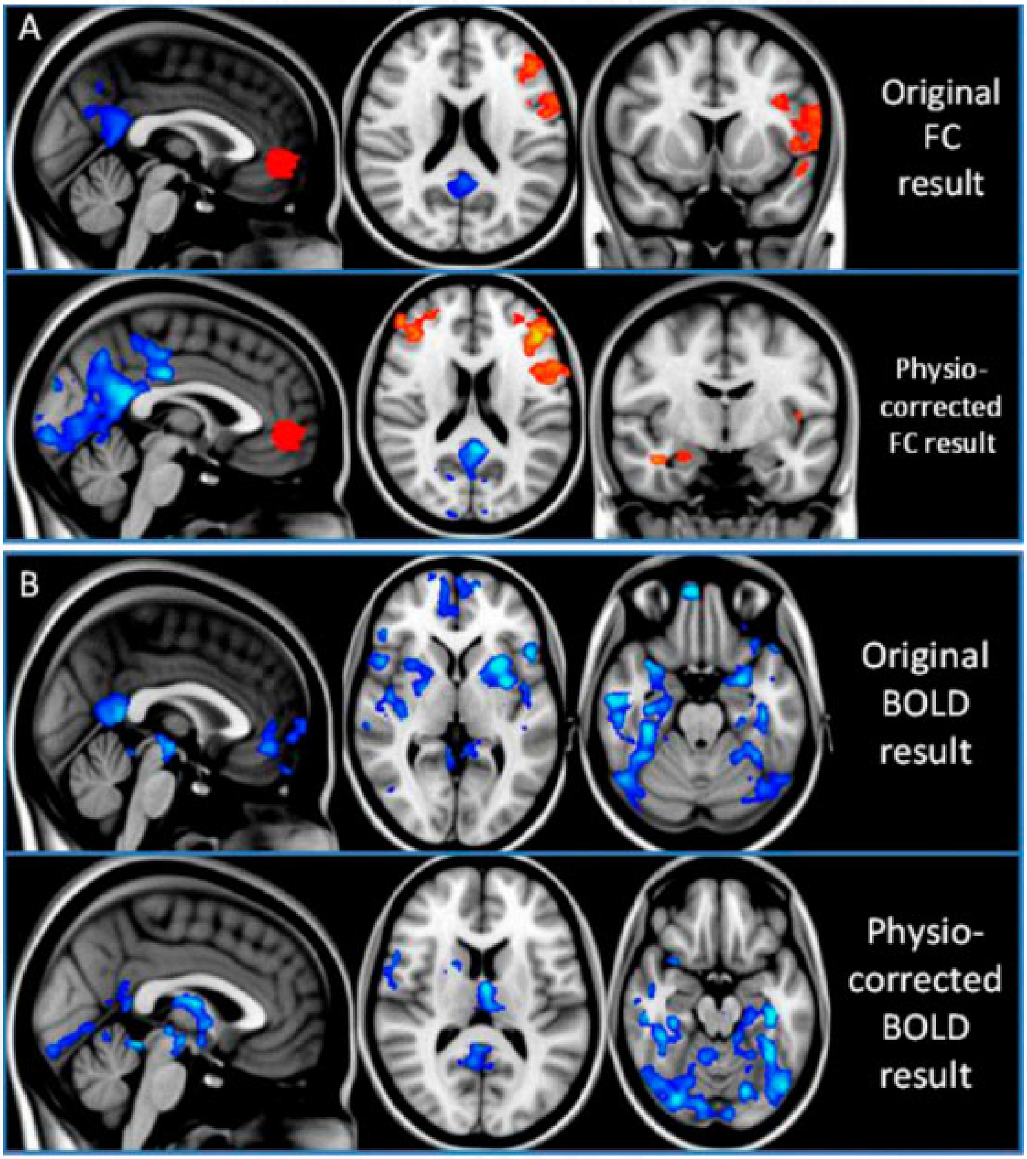


Fig. S3. Physiologically corrected results. (A) Corrected functional connectivity result. The original image used a cluster threshold of 2.3, mixed effects, $P < 0.05$, whole-brain corrected and the corrected image used a cluster threshold of 1.8, mixed effects, $P < 0.05$ whole-brain corrected. Both results show connectivity changes under psilocybin that were greater than connectivity changes under placebo (orange, increases in connectivity with the vmPFC; blue, decreases). (B) Corrected BOLD results. Both BOLD maps were based on mixed effects analyses, cluster-threshold 1.8, $P < 0.05$, whole-brain corrected. Both maps show greater decreases in BOLD after psilocybin vs. after placebo.

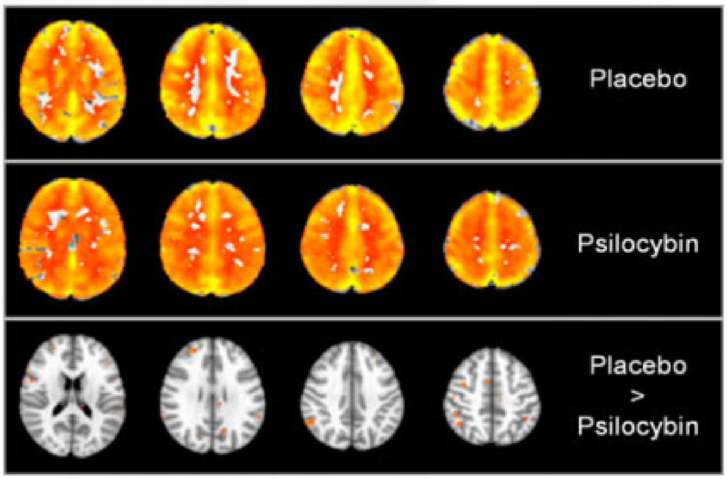

Fig. S4. Cerebrovascular reactivity (CVR) maps. The across-subject mean CVR maps are shown for both the placebo and psilocybin conditions (Top and Middle). Each map is thresholded at a very liberal $P < 0.01$ uncorrected threshold (t tests vs. 0). These maps demonstrate the high CVR values are located in gray matter as is expected. (Bottom) The results from a paired t test between placebo and drug conditions, again thresholded at $P < 0.01$ uncorrected. The paucity of differences at such a liberal threshold demonstrates that CVR remains unchanged by psilocybin.

Discussion

The fMRI studies reported here revealed significant and consistent outcomes. Psilocybin significantly decreased brain blood flow and venous oxygenation in a manner that correlated with its subjective effects, and significantly decreased the positive coupling of two key structural hubs (the mPFC and the PCC). Our use of fMRI to measure resting-state brain activity after a psychedelic is unique, and because the results are unexpected, they require some explanation.

The effect of psilocybin on resting-state brain activity has been measured before with PET and glucose metabolism [8]. This study found a global increase in glucose metabolism after oral psilocybin, which is inconsistent with our fMRI results. One possible explanation for this discrepancy relates to the fact that the radiotracer used to measure glucose metabolism (^{18}F-fluorodeoxyglucose) has a long half-life (110 min). Thus, the effects of psilocybin, as measured by PET, are over much greater timescales than indexed by our fMRI measures. It is therefore possible that phasic or short-term effects of psilocybin show some rebound that is detected by longer-term changes in glucose metabolism. More direct measures of neural activity will help inform this hypothesis, but in support of the inference that psilocybin does decrease neural activity, direct recordings of cortical local field potentials (LFPs) in rats found broadband decreases in resting state LFP power after psilocybin infusion - including γ-power[9] - changes in which are known to correlate with changes in the BOLD signal [10].

It has been commonly assumed that psychedelics work by increasing neural activity; however, our results put this into question. Psilocin is a mixed serotonin receptor agonist, but there is a general consensus that the characteristic subjective and behavioral effects of psychedelics are initiated via stimulation of serotonin 5-Hydroxytryptamine, 5-HT) 2A receptors[11]. It is possible that the deactivations observed in the present studies were caused by stimulation of 5-HT receptors other than 5-HT$_{2A}$; however, this seems unlikely given that the affinity of psychedelics for the 5- HT$_{2A}$ receptor correlates with their potency[12] and 5-HT$_{2A}$ antagonists block the subjective effects of psychedelics[13]. There is a large body of preclinical evidence that stimulation of 5-HT$_{2A}$ receptors increases GABAergic transmission and pyramidal cell inhibition[14-21], which may explain the deactivations observed here (Figs. 2 and 4). fMRI studies with serotonergic compounds that stimulate other 5-HT receptors, such as the 5-HT$_{2C}$[22] or (mainly) the 5-HT$_{1A}$ receptor[23], have not found comparable results to those shown here, and 5-HT$_{2A}$ receptors are present in high concentrations in the cortical regions that were significantly deactivated and decoupled after psilocybin (Table S2).

Stimulation of the 5-HT$_{2A}$ receptor increases excitation in the host cell by reducing outward potassium currents [24]. Thus, if the 5-HT$_{2A}$ receptor did mediate the observed deactivations, then it may have been via 5-HT$_{2A}$-induced excitation of fast-spiking interneurons terminating on pyramidal cells (e.g., ref. [24]) or 5-HT$_{2A}$-induced excitation of pyramidal cells projecting onto interneurons [25].

Regardless of how these effects were initiated at the receptor level, it is necessary for us to offer a functional explanation for them. It is noteworthy that the regions which showed the most consistent deactivations after psilocybin (e.g., the PCC and mPFC) are also those that show disproportionately high activity under normal conditions [26]. For example, metabolism in the PCC is ~20% higher than most other brain regions [27], yet psilocybin decreased its blood flow by up to 20% in some subjects. There is some mystery about the function of the PCC; its large size, buffered location, and rich vasculature means that it is well protected from damage. The high metabolic activity of the PCC and the default-mode network (DMN) with which is it associated [26] has led some to speculate about its functional importance, positing a role in consciousness [28] and high-level constructs, such as the self [29] or "ego" [30, 31]. Indeed, the DMN is known to be activated during self-referencing [28] and other high-level functions linked to the self-construct [27]. Moreover, DMN regions are also known to host the highest number of cortico-cortical connections in the brain, making them important "connector hubs" [32]. These hubs may be critical for efficient information transfer in the brain by allowing communication between different regions via the fewest number of connections [33]. However, such an integrative function would confer a significant responsibility on these regions, which may explain why their deactivation has such a profound effect on consciousness, as shown here.

Table S2. Regional 5-HT_{2A} receptor binding potentials: 5-HT_{2A} binding potential was assessed with ^{18}F-altanserin PET in 136 healthy adult human subjects

Brain region	BP_p(av)	SD
Posterior cingulate cortex	1.64	0.51
Superior temporal cortex	1.59	0.53
Medial inferior temporal cortex	1.57	0.52
Dorsolateral prefrontal cortex (DLPFC)	1.51	0.52
Anterior cingulate cortex	1.49	0.54
Medial inferior frontal gyrus	1.49	0.50
Occipital cortex	1.47	0.47
Orbitofrontal cortex	1.46	0.54
Paracingulate cortex	1.45	0.48
Average frontal cortex	1.45	0.50
Average global neocortex	1.44	0.48
Ventrolateral prefrontal cortex (VLPFC)	1.44	0.50
Insula	1.44	0.49
Superior frontal gyrus	1.38	0.48
Sensorimotor cortex	1.09	0.39
Amygdala	0.64	0.28
Putamen/pallidum	0.51	0.16
Hippocampus	0.51	0.28
Entorhinal cortex	0.43	0.32
Thalamus	0.33	0.18
Caudate nucleus	0.25	0.17

For further details about the data presented in the table, please see Erritzoe, et al.,[1] for study sample and imaging methods, Frokajer, et al.,[2] for delineation of VLPFC and DLPFC, and Svarer, et al.[3] for delineation of other brain regions. Please note that the VLPFC and the DLPFC are defined so that they are both overlapping with the medial and inferior frontal cortex, and in addition the DLPFC overlaps with the superior frontal cortex. Av, average; BPP, binding potential normalized to plasma; 5-HT, 5-Hydroxytryptamine.

These results may have implications beyond explaining how psilocybin works in the brain by implying that the DMN is crucial for the maintenance of cognitive integration and constraint under normal conditions. This finding is consistent with Aldous Huxley's "reducing valve" metaphor [34] and Karl Friston's "free-energy principle" [35], which propose that the mind/brain works to constrain its experience of the world.

The pharmaco-physiological interaction results were particularly intriguing, revealing significant decreases in the positive coupling between the PCC and mPFC after psilocybin. This result can be understood in terms of a regression of PCC activity on mPFC activity, in which the regression slope decreases. This finding can either be interpreted as a decrease in the (backward or top-down) connectivity from prefrontal to parietal regions or, equivalently, an increase in the reciprocal (forward or bottom-up) direction from parietal to prefrontal regions. This asymmetrical change in coupling, induced by psilocybin, is consistent with a reduction in the sensitivity of superficial pyramidal cells in the parietal region targeted by prefrontal afferents, which may or may not be associated with a compensatory increase in the influence of parietal regions on prefrontal activity. Whatever the underlying synaptic mechanisms, these results provide clear evidence for a perturbation in reciprocal coupling between these two association areas and speak to a rebalancing of hierarchical activity in distributed high-level modes.

Finally, consistent with their history of use as adjuncts to psychotherapy, the idea has recently re-emerged that psychedelics may be useful in the treatment of certain psychiatric disorders [36]. It seems relevant therefore that activity in [37] and connectivity with [38] the mPFC is known to be elevated in depression and normalized after effective treatment [39]. The mPFC was consistently deactivated by psilocybin (Fig. 4) and the magnitude of the deactivations correlated with the drug's subjective effects (Fig. 3). Depression has been characterized as an "overstable" state, in which cognition is rigidly pessimistic [39]. Trait pessimism has been linked to deficient 5-HT_{2A} receptor stimulation [40, 41], particularly in the mPFC [40], and mPFC hyperactivity has been linked to pathological brooding [42]. Recent work has shown that psilocybin can increase subjective well-being [4] and trait openness [43] several months after an acute experience, and depression scores in terminal cancer patients were significantly decreased 6 mo after treatment with psilocybin [2]. Our results suggest a biological mechanism for this: decreased mPFC activity via 5-HT_{2A} receptor stimulation. Further work is required to test this hypothesis and the putative utility of psilocybin in depression.

We also observed decreased CBF in the hypothalamus after psilocybin (Fig. 2), which may explain anecdotal reports that psychedelics reduce symptoms of cluster headaches [44]. Increased hypothalamic CBF was observed during acute headache in cluster headache sufferers [45] and inhibition of the hypothalamus via direct electrical stimulation can provide therapeutic relief for this condition [46].

To conclude, here we used an advanced and comprehensive fMRI protocol to image the brain effects of psilocybin. These studies offer the most detailed account to date on how the psychedelic state is produced in the brain. The results suggest decreased activity and connectivity in the brain's connector hubs, permitting an unconstrained style of cognition.

Materials and Methods

All subjects gave informed consent to participate in the study. The study was approved by a National Health Service research ethics committee. A physical examination, including electrocardiogram(ECG), routine blood tests, and urine test for drugs of abuse and pregnancy were carried out. A psychiatric assessment was conducted and participants disclosed their drug taking histories. Exclusion criteria were: less than 21 y of age, pregnancy, personal or immediate family history of psychiatric disorder, substance dependence, cardiovascular disease, claustrophobia, blood or needle phobia, or a significant adverse response to a hallucinogenic drug. All subjects had previous experience with a hallucinogenic drug but not within 6 wk of the study.

MRI Anatomical Scan

All imaging was performed on a 3T GE HDx system. For every functional scan, we obtained an initial 3D FSPGR scan in an axial orientation, with field of view= 256× 256× 192 and matrix = 256 × 256× 192 to yield 1-mm isotropic voxel resolution (TR/TE = 7.9/3.0 ms; inversion time = 450 ms; flip angle = 20°).

MRI Methods

ASL relative perfusion measurement

Whole-brain perfusion was measured using single-shot pulsed ASL PICORE (proximal inversion with a control for off-resonance effects) QUIPSSII (quantitative imaging of perfusion using a single subtraction) sequence with GE-EPI readout. The 240 tag-control image pairs with 16 axial slices (3 × 3 × 6-mm voxel resolution, matrix = 64 × 64, with a 1-mm gap in the axial direction) were acquired (TR/TE = 2200/19.8 ms, single-inversion time with TI1 = 700 and TI2 = 1,350 ms for the most proximal slice).

General linear modeling was used to evaluate the drug-induced modulation of the perfusion signal. In the first-level analysis, the difference between tag and control images was explicitly modeled as one regressor representing the voxel-wise mean perfusion per scan per voxel. A second regressor was established from the interaction of the first regressor and the estimated time-course based on the drug pharmacodynamics [5]. This represents the within-scan modulation of perfusion by the drug.

The results of fitting this model at the first level were combined in a higher level within-subjects analysis to compare modulation of perfusion during psilocybin infusion with that during saline infusion. A mixed-effects analysis was performed. Z statistical parametric maps were thresholded at a cluster size of $z > 2.3$ and a whole-brain significance of $P < 0.05$. To assist with this process, perfusion data underwent unwarping for B0 field distortions and were registered to the T1-weighted high-resolution (1 × 1 × 1 mm) structural scan which was itself registered to a 1-mm resolution Montreal Neurological Institute (MNI) standard brain, using nonlinear registration.

BOLD measurement

BOLD-weighted fMRI data were acquired using a gradient-echo EPI sequence, TR/TE 3000/35 ms, field-of-view = 192 mm, 64 × 64 acquisition matrix, parallel acceleration factor = 2, 90° flip angle. Fifty-three oblique-axial slices were acquired in an interleaved fashion, each 3 mm thick with zero slice gap (3 × 3 × 3-mm voxels). A total of 240 volumes were acquired.

At the first-level, a basic square function informed by the time-course of intravenous psilocybin's subjective effects [5] was used to model changes in the BOLD signal. A mixed-effects analysis was performed at the group level. Z statistical parametric maps were thresholded using clusters determined by $z > 2.3$ and a whole-brain cluster significance threshold of $P < 0.05$. The results were registered to the T1-weighted high-resolution (1 × 1 × 1 mm) structural scan, which was itself nonlinearly registered to a 1-mm MNI standard brain.

Pharmaco-Physiological Interaction/Functional Connectivity Analysis

A medial prefrontal ROI was drawn on a standard brain over maps of the CBF and BOLD decreases. This mask was then transformed into single-subject functional space and time series were derived for each subject. Gray matter, white matter, and CSF were segmented in each subjects' anatomical image and these masks were thresholded and transformed into functional space. Their time series were derived and used as regressors of no interest in the general linear model. The primary contrasts of interest within each subjects' scan was the interaction between vmPFC connectivity and the infusion event (i.e., maps were generated showing regions where activity became significant more and less coupled to activity in the vmPFC ROI after infusion versus before). Maps were generated for the effect of psilocybin infusion alone (Fig. 5, *Middle*) and psilocybin infusion versus placebo infusion (Fig. 5, *Bottom*). All maps were generated via mixed effects analyses, thresholded at a cluster size of 2.3, and whole-brain corrected for multiple comparisons with a P value of 0.05.

Physiological Noise Correction

After infusion of psilocybin, alterations in physiological rhythms, such as the respiration and cardiac cycle, may occur leading to changes in resting state BOLD signal fluctuations, thus biasing connectivity analyses. To adjust for such confounds, physiological correction routines were used. Respiration, cardiac, and end-tidal CO_2 traces were recorded during MR acquisitions using a chest bellows, a pulse oximeter, and a nasal canula attached to a capnograph, respectively. After extracting cycle timings, harmonics of the respiration and cardiac cycle (two respiration, two cardiac, and one interaction term) were removed from the data using RETROICOR (47). Variance because of cardiac and respiration rate changes was removed (48, 49) along with end-tidal CO_2-related fluctuations (50) using general linear model analyses.

Cerebrovascular Reactivity

Psilocybin may alter cerebrovascular reactivity (CVR), a blood vessel's ability to respond to a stimulus, thus introducing a bias between conditions. To determine if changes in reactivity occur, MR measurements of CVR were acquired using the approach of Murphy *et al.* [7]. Briefly, participants were asked to perform a breath-hold task (30-s paced breathing, 10-s breath-hold) while MR data with a similar acquisition to above and end-tidal CO_2 traces were acquired. BOLD responses to breath-hold were normalized to subject-specific CO_2 increases to give percent BOLD/mmHg, a CVR measure. These maps were transformed into MNI space and voxel-wise paired t tests were performed between the placebo and psilocybin conditions.

Abstract: The study of rapid changes in brain dynamics and functional connectivity (FC) is of increasing interest in neuroimaging. Brain states departing from normal waking consciousness are expected to be accompanied by alterations in the aforementioned dynamics. In particular, the psychedelic experience produced by psilocybin (a substance found in "magic mushrooms") is characterized by unconstrained cognition and profound alterations in the perception of time, space and selfhood. Considering the spontaneous and subjective manifestation of these effects, we hypothesize that neural correlates of the psychedelic experience can be found in the dynamics and variability of spontaneous brain activity fluctuations and connectivity, measurable with functional Magnetic Resonance Imaging (fMRI). Fifteen healthy subjects were scanned before, during and after intravenous infusion of psilocybin and an inert placebo. Blood-Oxygen Level Dependent (BOLD) temporal variability was assessed computing the variance and total spectral power, resulting in increased signal variability bilaterally in the hippocampi and anterior cingulate cortex. Changes in BOLD signal spectral behavior (including spectral scaling exponents) affected exclusively higher brain systems such as the default mode, executive control, and dorsal attention networks. A novel framework enabled us to track different connectivity states explored by the brain during rest. This approach revealed a wider repertoire of connectivity states post-psilocybin than during control conditions. Together, the present results provide a comprehensive account of the effects of psilocybin on dynamical behavior in the human brain at a macroscopic level and may have implications for our understanding of the unconstrained, hyper-associative quality of consciousness in the psychedelic state.

Key words: Psilocybin; fMRI; functional connectivity; resting state; psychedelic state

INTRODUCTION

Psilocybin (phophoryl-4-hydroxy-dimethyltryptamine) is the phosphorylated ester of the main psychoactive compound found in magic mushrooms. Pharmacologically related to the prototypical psychedelic LSD, psilocybin has a long history of ceremonial use via mushroom ingestion and, in modern times, psychedelics have been assessed as tools to enhance the psychotherapeutic process [Grob *et al*., 2011; Krebs *et al*., 2012; Moreno *et al*., 2006]. The subjective effects of psychedelics include (but are not limited to) unconstrained, hyperassociative cognition, distorted sensory perception (including synesthesia and visions of dynamic geometric patterns) and alterations in one's sense of self, time and space. There is recent preliminary evidence that psychedelics may be effective in the treatment of anxiety related to dying [Grob *et al*., 2011] and obsessive compulsive disorder [Moreno *et al*., 2006] and there are neurobiological reasons to consider their potential as antidepressants [Carhart-Harris *et al*., 2012, 2013]. Similar to ketamine (another novel candidate antidepressant) psychedelics may also mimic certain psychotic states such as the altered quality of consciousness that is sometimes seen in the onset-phase of a first psychotic episode [Carhart-Harris *et al*., 2014]. There is also evidence to consider similarities between the psychology and neurobiology of the psychedelic state and Rapid Eye Movement (REM) sleep [Carhart-Harris, 2007; Carhart-Harris and Nutt, 2014], the sleep stage associated with vivid dreaming [Aserinsky and Kleitman, 1953].

The potential therapeutic use of psychedelics, as well as their capacity to modulate the quality of conscious experience in a relatively unique and profound manner, emphasizes the importance of studying these drugs and how they act on the brain to produce their novel effects. One potentially powerful way to approach this problem is to exploit human neuroimaging to measure changes in brain activity during the induction of the psychedelic state. The neural correlates of the psychedelic experience induced by psilocybin have been recently assessed using Arterial Spin Labeling (ASL) and BOLD fMRI [Carhart-Harris *et al*., 2012]. This work found that psilocybin results in a reduction of both CBF and BOLD signal in major subcortical and cortical hub structures such as the thalamus, posterior cingulate (PCC) and medial prefrontal cortex (mPFC) and in decreased resting state functional connectivity (RSFC) between the normally highly coupled mPFC and PCC. Furthermore, our most recent study used magnetoencephalography (MEG) to more directly measure altered neural activity post-psilocybin and here we found decreased oscillatory power in the same cortical hub structures [Muthukumaraswamy *et al*., 2013, see also Carhart-Harris *et al*., 2014 for a review on this work).

These results establish that psilocybin markedly affects BOLD, CBF, RSFC, and oscillatory electrophysiological measures in strategically important brain structures, presumably involved in information integration and routing [Carhart-Harris *et al*., 2014; de Pasquale *et al*., 2012; Hagmann *et al*., 2008; Leech *et al*., 2012]. However, the effects of psilocybin on the variance of brain activity parameters across time has been relatively understudied and this line of enquiry may be particularly informative in terms of shedding new light on the mechanisms by which psychedelics elicit their characteristic psychological effects. Thus, the main objective of this article is to examine how psilocybin modulates the dynamics and temporal variability of resting state

BOLD activity. Once regarded as physiological noise, a large body of research has now established that resting state fluctuations in brain activity have enormous neurophysiological and functional relevance [Fox and Raichle, 2007]. Spontaneous fluctuations self-organize into internally coherent spatiotemporal patterns of activity that reflect neural systems engaged during distinct cognitive states (termed "intrinsic" or "resting state networks" - RSNs) [Fox and Raichle, 2005; Raichle, 2011; Smith *et al.*, 2009]. It has been suggested that the variety of spontaneous activity patterns that the brain enters during task-free conditions reflects the naturally itinerant and variegated quality of normal consciousness [Raichle, 2011]. However, spatio-temporal patterns of resting state activity are globally well preserved in states such as sleep [Boly *et al.*, 2009, 2012; Brodbeck *et al.*, 2012; Larson-Prior *et al.*, 2009; Tagliazucchi *et al.*, 2013a,b,c] in which there is a reduced level of awareness - although very specific changes in connectivity occur across NREM sleep, allowing the decoding of the sleep stage from fMRI data [Tagliazucchi *et al.*, 2012c; Tagliazucchi and Laufs, 2014]. Thus, if the subjective quality of consciousness is markedly different in deep sleep relative to the normal wakeful state (for example) yet FC measures remain largely preserved, this would suggest that these measures provide limited information about the biological mechanisms underlying different conscious states. Similarly, intra-RSN FC is decreased under psilocybin [Carhart-Harris *et al.*, 2013] yet subjective reports of unconstrained or even "expanded" consciousness are common among users (see Carhart-Harris *et al.* [2014] for a discussion). Thus, the present analyses are motivated by the view that more sensitive and specific indices are required to develop our understanding of the neurobiology of conscious states, and that measures which factor in variance over time may be particularly informative.

A key feature of spontaneous brain activity is its dynamical nature. In analogy to other self-organized systems in nature, the brain has been described as a system residing in (or at least near to) a critical point or transition zone between states of order and disorder [Chialvo, 2010; Haimovici *et al.*, 2013; Tagliazucchi and Chialvo, 2011; Tagliazucchi *et al.*, 2012a]. In this critical zone, it is hypothesized that the brain can explore a maximal repertoire of its possible dynamical states, a feature which could confer obvious evolutionary advantages in terms of cognitive and behavioral flexibility. It has even been proposed that this cognitive flexibility and range may be a key property of adult human consciousness itself [Tononi, 2012]. An interesting research question therefore is whether changes in spontaneous brain activity produced by psilocybin are consistent with a displacement from this critical point - perhaps towards a more entropic or supercritical state (i.e. one closer to the extreme of disorder than normal waking consciousness) [Carhart-Harris *et al.*, 2014]. Further motivating this hypothesis are subjective reports of hyper-associative cognition under psychedelics, indicative of unconstrained brain dynamics. Thus, in order to test this hypothesis, it makes conceptual sense to focus on variability in activity and FC parameters over time, instead of the default procedure of averaging these over a prolonged period. In what follows, we present empirical data that tests the hypothesis that brain activity becomes less ordered in the psychedelic state and that the repertoire of possible states is enhanced. After the relevant findings have been presented, we engage in a discussion to suggest possible strategies that may further characterize quantitatively where the "psychedelic brain" resides in state space relative to the dynamical position occupied by normal waking consciousness.

MATERIALS AND METHODS

Study Overview and Design

This was a within-subjects placebo-controlled study. The study was approved by a local NHS Research Ethics Committee and University of Bristol Research and Development department, and conducted in accordance with Good Clinical Practice guidelines. A Home Office License was obtained for storage and handling of a Schedule 1 drug and the University of Bristol sponsored the research.

Participants

This is a new analysis on previously published data [Carhart-Harris *et al.*, 2012, 2013]. Fifteen healthy subjects took part: 13 males and 2 females (mean age = 32, SD = 8.9). Recruitment was via word of mouth. All subjects were required to give informed consent and undergo health screens prior to enrollment. Study inclusion criteria were: at least 21 years of age, no personal or immediate family history of a major psychiatric disorder, substance dependence, cardiovascular disease, and no history of a significant adverse response to a hallucinogenic drug. All of the subjects had used psilocybin at least once before (mean number of uses per subject = 16.4, SD = 27.2) but not within 6 weeks of the study.

Anatomical Scans

Image acquisition was performed on a 3T GE HDx system. Anatomical scans were performed before each functional scan and thus during sobriety. These were three-dimensional fast spoiled gradient echo scans in an axial orientation, with field of view = 256 x 256 x 192 and matrix = 256 x 256 x 192 to yield 1 mm isotropic voxel resolution (repetition time/echo time [TR/TE] = 7.9/3.0 ms; inversion time = 450 ms; flip angle = 20°).

Drug Infusion

All subjects underwent two 12 min eyes closed resting state BOLD fMRI scans on two separate occasions at least 7 days apart: placebo (10 ml saline, 60 s intravenous injection) was given on one occasion and psilocybin (2 mg dissolved in 10 ml saline, 60 s infusion) on the other. Seven of the subjects received psilocybin in scan 1, and 8 received it in scan 2. Injections were given manually by a doctor within the scanning suite. The 60 s infusions began exactly 6 min after the start of the 12 min scans. The subjective effects of psilocybin were felt almost immediately after injection and were sustained for the remainder of the RS scan. For more details on the subjective effects of intravenous psilocybin see [Carhart-Harris *et al*., 2012, 2013].

fMRI Data Acquisition and Preprocessing

BOLD-weighted fMRI data were acquired using a gradient echo planar imaging sequence, TR/TE 3,000/35 ms, field-of-view = 192 mm, 64 x 64 acquisition matrix, parallel acceleration factor = 2, 90° flip angle. Fifty-three oblique axial slices were acquired in an interleaved fashion, each 3 mm thick with zero slice gap (3 x 3 x 3 mm voxels). A total of 240 volumes were acquired, with infusion taking place in the middle of the session. Data were motion corrected using FSL MCFLIRT and a high-pass filter of 100 s was applied. Data were smoothed using a Gaussian kernel of 5 mm FWHM. Motion time courses were regressed from the data during the preprocessing step, together with average CSF and white matter time courses. As an additional control to exclude epochs of large movement amplitude, all volumes associated with a mean head displacement larger than 1 SD were erased from the analysis.

Analysis of Spatiotemporal Dynamics

The methods here employed are based on a statistical physics framework useful for characterizing fluctuations in systems composed of large number of coupled degrees of freedom. From this perspective, fluctuating activity in a particular region and correlations between different regions are interdependent or related [Ross, 1966]. Therefore, any change in the cortical dynamics due to a given intervention is expected to be reflected both at the level of the variance of the activity at one region and in the strength of the interactions between different regions. In what follows, the methodology accounting for these two aspects (i.e. the temporal variability and the dynamical changes in correlations) are explained in detail. All the numerical analyses for these calculations were performed using in-house MATLAB scripts.

Analysis of Temporal Variability

The analysis referred to here as "temporal variability" is concerned with the variance in the amplitude of the BOLD signal and it can be expressed both in a temporal (i.e., the standard variance) and frequency domain, as will be explained below. As a time domain measure of variability in the amplitude of the BOLD signal, straightforward voxel-wise computation of BOLD variance was performed, resulting in whole-brain BOLD variance maps for each condition (psilocybin/placebo before and after infusion) and participant. An additional evaluation of variance can be performed in the frequency domain, noting that by Parseval's theorem:

$$\int x^2(t)dt = \int |A(f)|^2 df \tag{1}$$

Then, the following series of equalities holds (for a signal with zero mean):

$$\sigma^2 = \lim_{T\to\infty} \frac{1}{T}\int_{-T/2}^{T/2} x^2(t)dt = \lim_{T\to\infty} \frac{1}{T}\int |A(f)|^2 df = \int \Phi(f)df \tag{2}$$

In Eqs. (1) and (2), $A(f)$ represents the Fourier transform of $x(t)$ and $\Phi(f)$ is the power spectral density. Therefore, the variance can also be obtained by integrating $\Phi(f)$ across the whole range of frequencies.

Further Spectral Analysis of BOLD Fluctuations

Equations (1) and (2) show that the integral of the power spectral density equals the variance of the signal. If this integral is not performed across all frequencies but in a certain range, the result will correspond to the contribution of the frequencies to the variance in the specified ranges. It is generally considered that slow (0.01-0.1 Hz) BOLD frequencies carry neural significance in the resting state fMRI signal [Cordes *et al.*, 2001], therefore, we evaluated separately the low frequency power (LFP) in this range and compared it before and after the psilocybin infusion.

Given the fact that the spectral content of spontaneous BOLD fluctuations, like many other complex systems in nature, follows a power law of the form $1/f^{\alpha}$ [Expert *et al.*, 2011], its power spectrum density can also be characterized by a single parameter (α). This parameter condenses the scaling behavior and is demonstrative of the longrange temporal correlations (or memory) of any given signal. Thus, for uncorrelated noise, $\alpha = 0$ (i.e. a flat spectrum, or so called "white noise") is obtained, whereas for signals presenting some degree of long-term correlations, values of $\alpha > 0$ (i.e., the so called "colored noise") are observed. To obtain the scaling exponent α, the first derivative of BOLD time series was first computed (in order to minimize the influence of nonstationarities) and the fit was performed on the spectrum of the derivative. Note that for a power spectrum of the form $1/f^{\alpha}$, differentiation decreases the value of α by 2, so the exponent of the original time series can be recovered from that of the derivative.

Point-Process Analysis

A recent series of studies demonstrated that the continuous BOLD signal can be transformed into a discrete point-process encoding the timings of the most functionally relevant events [Petridou *et al.*, 2012, Davis *et al.*, 2013; Tagliazucchi *et al.*, 2010a,b, 2012a]. In this approach, relevant events are defined by a threshold crossing (e.g. whenever the signal departs + SD from its mean value). Besides allowing a dramatic compression of the information present in a BOLD timeseries, this approach has the particular benefit of allowing a simple criterion to eliminate motion artifacts: i.e. "points" (threshold crossings) occurring during high movement epochs (i.e. larger than a certain value) are simply ignored in the analysis.

Two interdependent observables are defined once the point-process is obtained: the rate (number of crossings divided by the series length) and inter-event intervals (average temporal separation between two consecutive points). On average, there is a clear inverse relationship between these two variables. Furthermore, the rate is expected to increase (or the interval to decrease) for a signal with a high contribution of fast frequencies.

As an efficient alternative to the spectral analysis described in the previous section, we computed the voxel-wise distribution of rates and intervals and compared it between the different conditions.

Computation of Dynamical Functional Connectivity States and its Associated Entropy

As already discussed above, for spatio-temporal fluctuations arising from the dynamics of large scale systems, the relation between the temporal fluctuations of the average signal and its spatial correlation function is well defined [Ross, 1966]. It is known that under general assumptions, the mean field peak-to-peak amplitude of a signal (or its variance) is directly proportional to its mean correlation value. Intuitively, this is analogous to the principle that synchronized/desynchronized clapping produces stronger/weaker collective effects. Therefore, to complement the investigation of regional changes in the variance of the BOLD signal in various regions of the cortex, it is logical to also look at measures of the mean functional correlations between participating regions. Given the highly transient nature of these correlations, we term these indices "dynamical functional connectivity states". They are computed as follows (see Fig. 4 for an illustration of the general procedure).

MNI coordinates	AAL region	Hemisphere	*t*-value
BOLD variance (after psilocybin > before psilocybin)			
(-34, -22, -16)	Hippocampus	Left	4.51
(26, -22, -16)	Hippocampus	Right	3.54
(-2, 22, 28)	Anterior cingulate	Left	3.72
(4, 34, 18)	Anterior cingulate	Right	3.74
BOLD total spectral power (after psilocybin > before psilocybin)			
(32, -14, -13)	Hippocampus	Right	4.03
(-26, -18, -15)	Hippocampus	Left	4.39
(-26, 1, 38)	Parahippocampal Gyrus	Left	4.77
(37, -2, -38)	Parahippocampal Gyrus	Right	4.55
(7, 27, 17)	Anterior cingulate	Right	4.02
(-7, 43, -2)	Anterior cingulate	Left	4.12

Table I: Regions corresponding to local maxima of statistical significance (provided they are more than 8 mm apart) for increased cortical BOLD variance and total spectral power after psilocybin infusion (compared to before psilocybin infusion).
Montreal Neurological Institute (MNI) coordinates and Automatic Anatomical Labeling (AAL) regions are provided.

The BOLD time series is first divided into M non-overlapping windows of length L. Then, the partial correlation values between a set of N brain regions of interest is computed inside each temporal window as follows,

$$R_C(X, Y) = \min R(X, Y|Z) \tag{3}$$

where $R(X, Y|Z)$ is defined as follows,

$$R(X,Y|Z) = \frac{R(X,Y) - R(Y,Z)}{\sqrt{1 - R(X,Z)^2}} \tag{4}$$

In Eq. (3), the minimum is taken across all signals Z different from X,Y. In Eq. (4), $R(X, Y)$ represents the linear correlation between variables X and Y. Thus, the partial correlation RC(X,Y) measures the correlation of both variables removing the effect of a set of controlling variables. In what follows, the set of variables will include all BOLD signals from the N brain regions under study plus the time series of absolute head displacement (to remove spurious correlations), as estimated during the motion correction step. Finally, for each pair of regions a link is established between them if the correlation P value is significant at the level of $P < 0.05$, Bonferroni corrected (N (N - 1)/2). Performing this computation for all temporal windows gives the temporal evolution of the connectivity graph.

For N brain regions, the total number of dynamical functional connectivity graphs (i.e. all possible connectivity motifs) equals $2^{(N(N-1)/2)}$. For example, for $N = 3, 4, 5$, the number of states is 8, 64, 1,024. Once the dynamical functional connectivity states are obtained by the procedure above described, a symbolization procedure can be used to map the limited amount of states into discrete symbols (a bijection or one-to-one mapping of each temporal sequence of states into "words" - whose letters represent the different connectivity graphs). Then, the entropy of this sequence can be computed using the straightforward definition of Shannon's entropy:

$$H = \sum_{i=1}^{N(N-1)/2} p_i \log(1/p_i) \tag{5}$$

where p_i is the probability of the ith state occurring in the sequence. We evaluate the entropy of dynamical functional connectivity states in the network of regions of peak statistical significance presented in Table I and Figure 1 (i.e., the left and right hippocampus and ACC). This choice is motivated by the well-known observation that, for a system of coupled elements, the temporal variability of the activity time series is driven by variability in the collective interactions [Ross, 1966]. This process resulted in four regions and a total of 64 connectivity states (i.e. the number of possible dynamical interaction motifs between the four nodes).

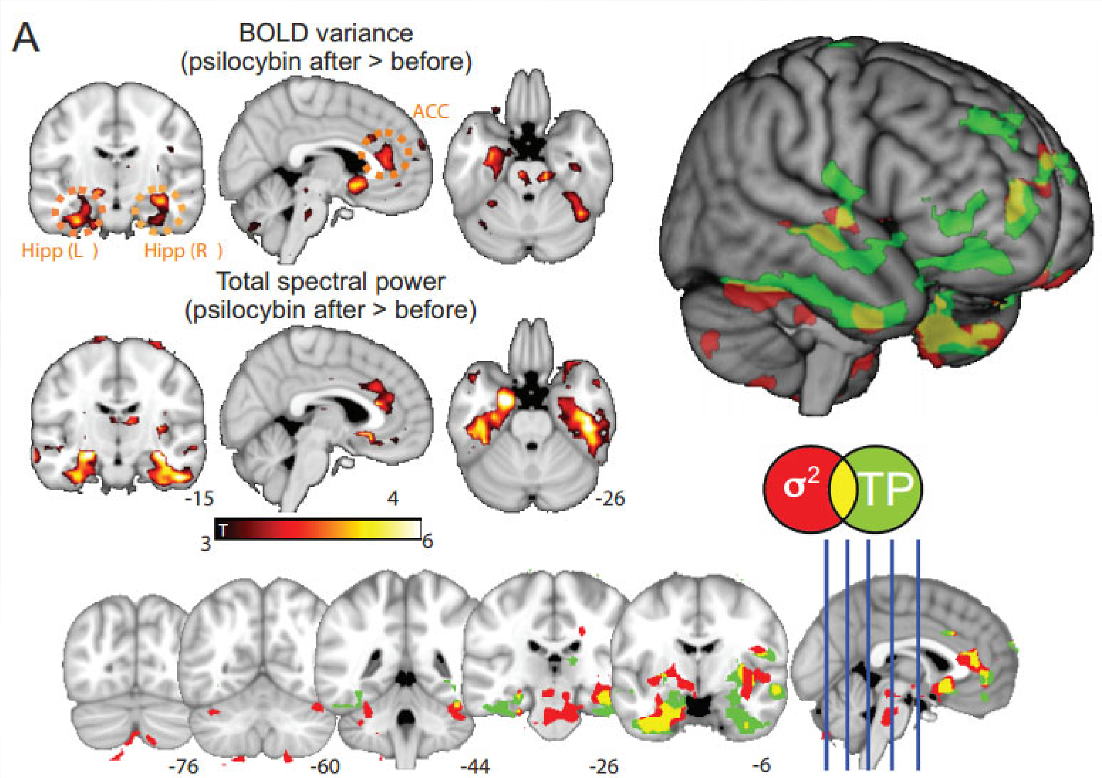

Figure 1. Psilocybin infusion modifies the temporal variability of BOLD signal in a network comprising anterior cingulate cortex (ACC) and bilateral hippocampus. **A**) Maps of statistical significance for variance (σ^2) and total spectral power (TP) increases after psilocybin infusion. Results are shown overlaid separately into an anatomical MNI152 template, overlaid together and also rendered together into a threedimensional anatomical image. In all cases only clusters surviving a threshold of $P < 0.05$, Family Wise Error (FWE) cluster corrected (after passing an uncorrected threshold of $P < 0.005$) are shown.

Statistical Testing

To perform statistical significance testing, a paired *t*-test was used, as implemented in SPM8. Only clusters passing a threshold of $P < 0.05$ Family Wise Error (FWE) corrected for multiple comparisons were considered significant. For display purposes, significance maps were thresholded at $P < 0.005$, showing only clusters passing the above mentioned criterion. Significance testing for the entropy differences reported in Figure 5 was also evaluated using a paired *t*-test.

RESULTS

The statistical significance maps for the BOLD signal variance and total spectral power can be found in Figure 1A and the significance peaks are summarized in Table I (in this and the following sections, unless explicitly stated no differences were found by examining the opposite contrasts). Both measures show increased variability following psilocybin administration - both in the temporal and spectral domain - with peaks in the anterior cingulate cortex and bilateral hippocampus (total spectral power is also increased in the bilateral parahippocampal gyri). As shown in Figure 1 there is a large overlap in the regions affected by both measures, as can be expected from Eq. (2). The differences found for the power spectral estimation in the parahippocampal gyrus are not apparent for the variance. Most likely this discrepancy is due to the numerical evaluation of these two equivalent quantities.

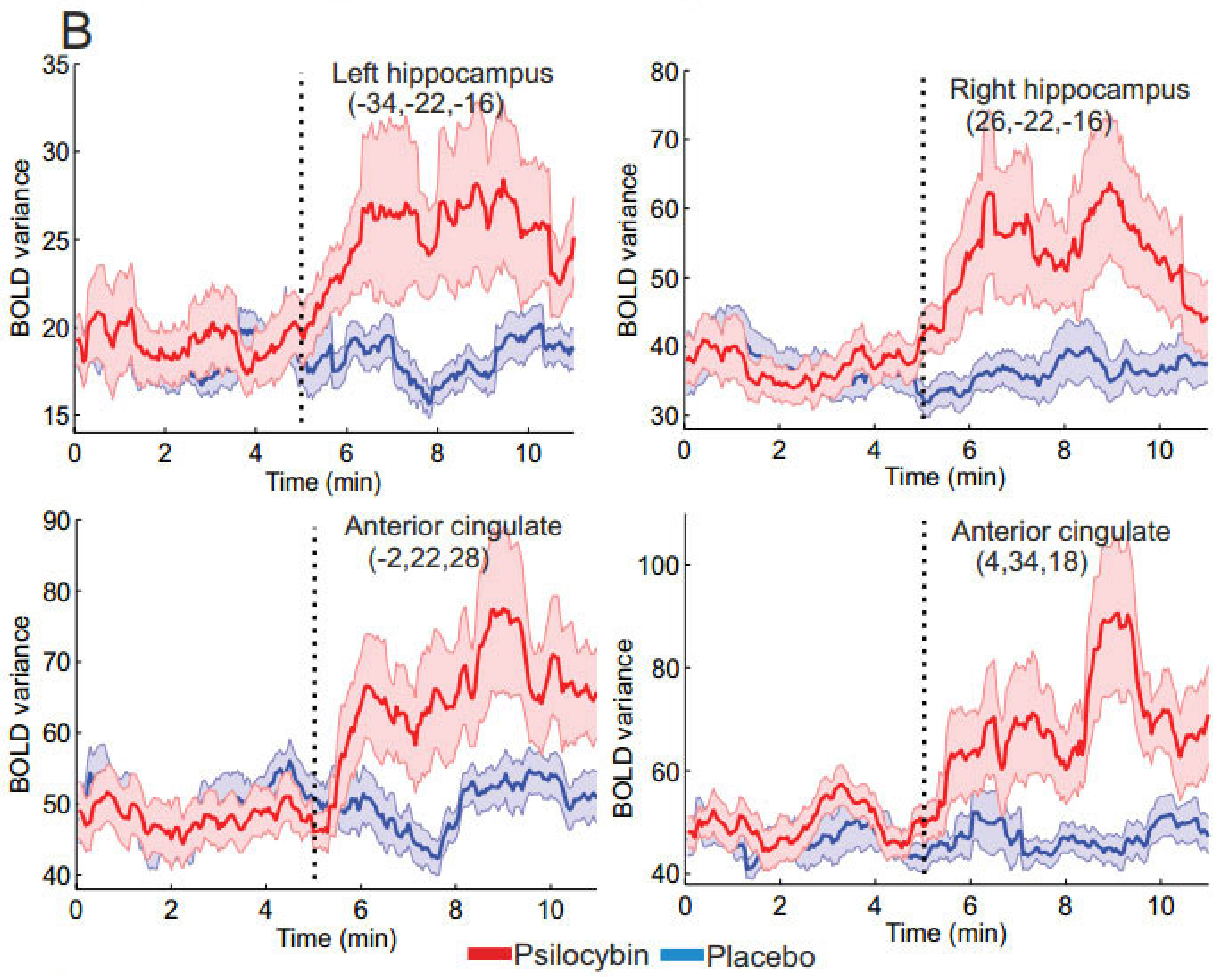

Figure 1B. BOLD Variance time courses (obtained over a 1 min. sliding window) into the four regions of peak statistical significance defined in Table I for the psilocybin and the placebo infusion.

To find the temporal evolution of the variance increases, we selected the four significance peaks for BOLD variance as ROIs (Table I) and used a sliding window analysis (1 min. window length) to compute the evolution of the variance. Since these ROI are selected as regions of high variance, it is already known that fluctuations in their activity will have an increased variance relative to baseline. However, this analysis provides additional information about when those increases occurred (e.g. just after the psilocybin infusion or later). In Figure 1B the results of this analysis are presented. A homogeneous increase in signal variance is observed during the first 3 min post-psilocybin infusion, with a tendency to plateau or slightly decrease afterwards. A longer experiment would be needed to confirm the persistence of this effect, but it does seem to correspond well with the known pharmaco-dynamics of intravenous psilocybin, i.e. subjects reported the most intense subjective effects within the first 3 min of the infusion and the effects were persistent for the duration of the scan [Carhart-Harris *et al*., 2012, 2013].

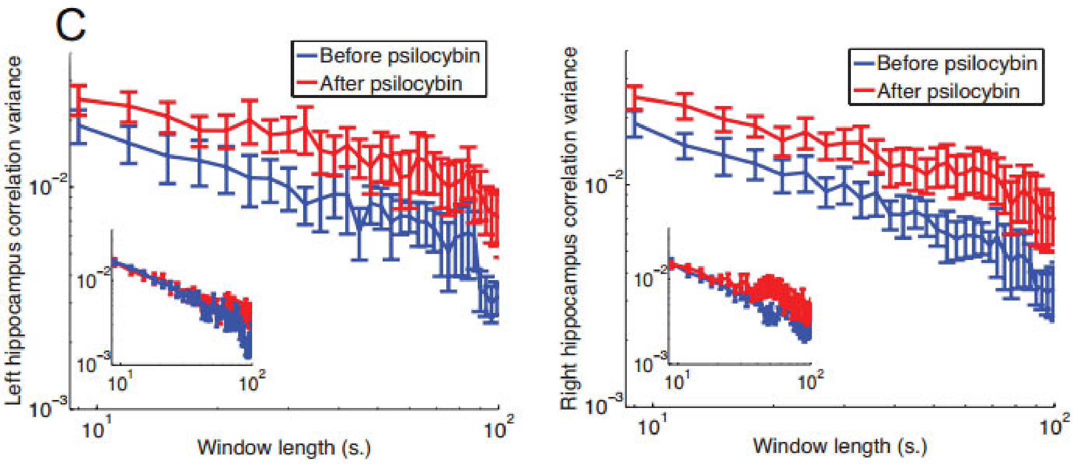

Figure 1C. Variance of the time course of intra-hippocampal correlations (computed over a range of non-overlapping window lengths) before and after psilocybin infusion. Results for placebo infusion are shown as insets (before and after in blue and red, respectively).

We also studied the variance of intra-hippocampal connectivity time courses, computed as the linear correlation of all hippocampal voxels over nonoverlapping windows of different lengths. Results are shown in Figure 1C. It can be seen that the variance is higher in both hippocampi after the psilocybin infusion.

Next, we studied the spectral content of spontaneous BOLD fluctuations. This was done by computing the low frequency (0.01-0.1 Hz) power (LFP) and the power spectrum scaling exponent (α). Statistical significance maps are presented in Figure 2A and statistical significance peaks in Table II.

Figure 2. Psilocybin infusion modifies BOLD spectral content in a distributed fronto-parietal network. **A**) Maps of statistical significance for decreased low frequency power (LFP) and power spectrum scaling exponent α after psilocybin infusion. Results are shown overlaid separately into an anatomical MNI152 template, overlaid together and also rendered together into a threedimensional anatomical image. Notice that in all cases only clusters surviving a threshold of $P < 0.05$, FWE cluster corrected (after passing an uncorrected threshold of $P < 0.005$) are shown.

After psilocybin infusion, diffuse widespread decreases in LFP and the scaling exponent α were observed in frontal and parietal regions. Changes in LFP and the scaling exponent (α) were found consistently in the same spatial locations, which is expected since a scaling closer to that of uncorrelated noise (i.e. an α value closer to 0) will result in weaker low frequency spectral power. These effects were confined to the post-psilocybin period. No differences were found when performing the same comparison in the placebo condition.

To further characterize BOLD fluctuations, we transformed whole brain signals into a spatio-temporal pointprocess and extracted two statistics: the rate (average number of events) and the interval (average separation between two events). By the very definition of the pointprocess, a signal with high power in fast frequencies will give a high rate and therefore a low separation between events i.e., the average interval will be small. Results shown in Figure 2B confirm this observation. Statistical significance peaks are presented in Table III. A rate increase and interval decrease after psilocybin was observed in parietal and frontal regions largely overlapping with those of Figure 2A. No differences were found when performing the same comparison in the placebo condition.

Figure 2B. Maps of statistical significance of increased power point rate (PPR) and decreased point process interval (PPI) after psilocybin infusion (same renderings and statistical thresholds as in A).

To identify the brain networks associated with the changes shown in Figure 2A,B, we computed the overlap of the statistical significance maps with a set of well-established Resting State Networks (RSNs) [Beckmann and Smith, 2004; Beckmann *et al.*, 2005]. These included: two visual (medial and lateral), an auditory, sensori-motor, default mode, executive control and two lateralized dorsal attention networks.

To compute the overlap for a given map, we counted the number of voxels included in each RSN and normalized by the total number of voxels in the RSN mask. Using this approach, larger maps present a higher chance of having large overlaps, therefore, we constructed a null-hypothesis by randomizing the phases of the maps (after transforming to Fourier space), resulting in images with the same second order statistics [see also Tagliazucchi *et al.*, 2013c]. A total of 100 randomizations were performed for each comparison and an empirical p-value was constructed, counting the ratio of instances in which the real overlap exceeded the overlap computed with the randomized map. The results of these analyses are presented in Figure 3. For LFP and α, significant overlaps were detected in the default mode, control and attention networks, whereas all sensory networks remained unaffected. For the point-process rate (PPR) and point-process interval (PPI) the changes were locally confined to the default mode network.

Next, the dynamic functional connectivity states were obtained from the set of regions showing increased temporal variability (Fig. 1 and Table I) by applying the analysis outlined in Figure 4. Using different window lengths (ranging from 15 to 150 s.) we evaluated the entropy of the distribution of connectivity states in the network comprised by two ACC ROIs and the bilateral hippocampi. An entropy increase was found when comparing the results between the periods before and after the psilocybin infusion and after the psilocybin infusion vs. after the placebo infusion, but no changes were observed when comparing before and after placebo (see Fig. 5A). The entropy increase was not seen for very short window lengths but was manifest for all lengths larger than approximately 1 min.

Tabela III: Regions corresponding to local maxima of statistical significance (provided they are more than 8 mm apart) for increased cortical point-process rate (PPR) and decreased point-process interval (PPI) after psilocybin infusion (compared to before psilocybin infusion).

The most frequent states in each condition are shown in Figure 5B. These have sparse connectivity and represent functional connections between homologous ROIs and between ROIs in the same hemisphere, but cross-hemisphere connections between hippocampal and ACC ROIs also appear in the psilocybin condition. The psilocybin state is also characterized by a larger repertoire of states: i.e. novel motifs that are exclusive to the psychedelic state and which are shown in the last row of Figure 5B. These motifs are among the most interconnected states possible.

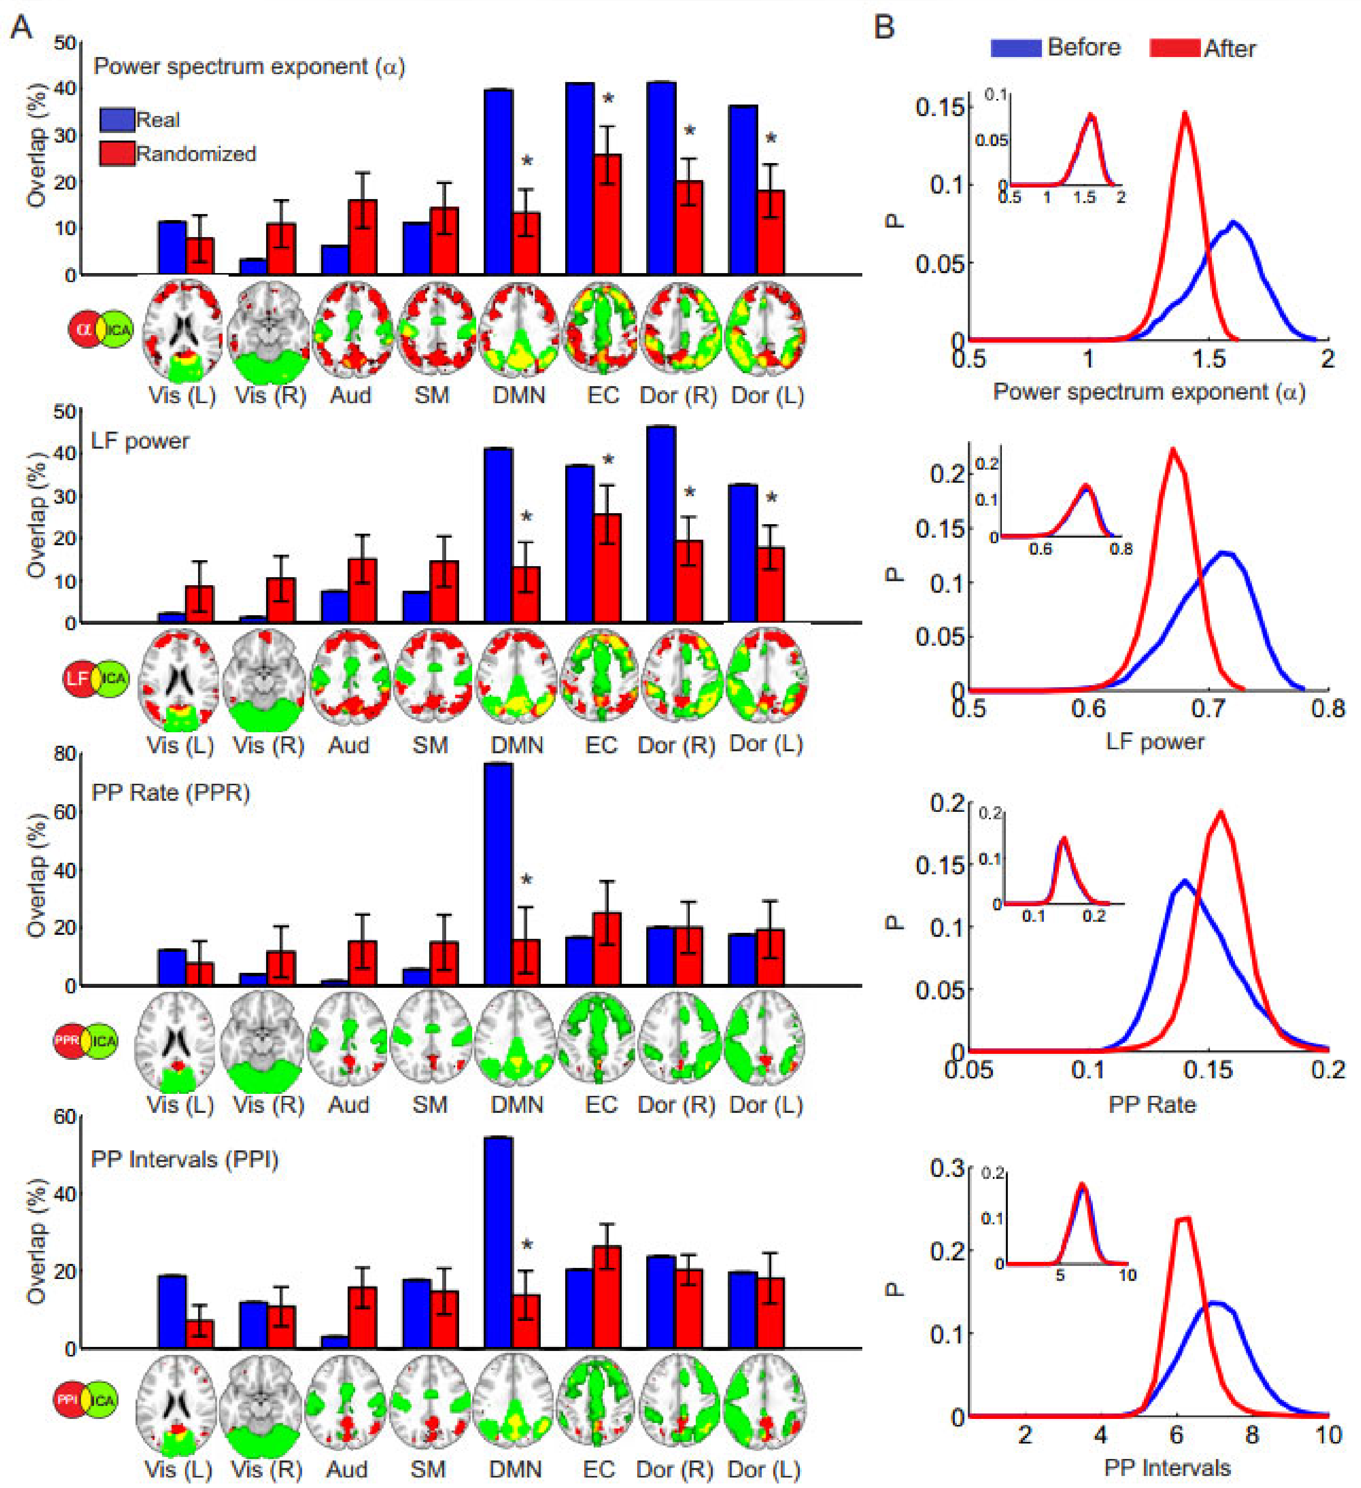

Figure 3. BOLD spectral changes after psilocybin infusion are located in higher order brain networks and leave primary sensory areas unaffected. **A**) Overlap between statistical significance maps presented in Figure 2 and a group of well-established cortical RSN (from Beckmann *et al*. [2005]) together with the average overlap obtained after 100 spatial randomizations preserving first order statistics (image phase shuffling). (*) indicates an empirical *P* value smaller than 0.05, Bonferroni corrected. This *P* value is defined as the ratio of instances in which the real maps yield a higher overlap than the randomized versions. **B**) Whole brain grey matter average probability distributions for α, LFP, PPR, and PPI, before and after psilocybin infusion. In the inset, the same distributions are shown before and after the placebo infusion.

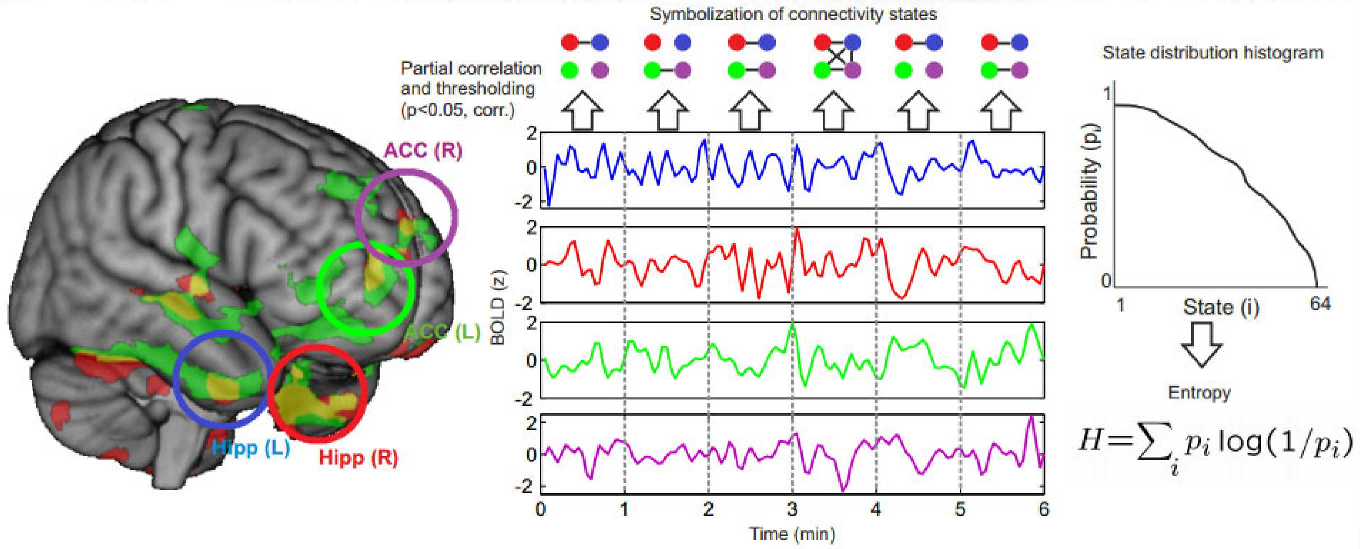

Figure 4. Entropy of the dynamical functional connectivity states. Illustration of the procedure to estimate the temporal evolution of the collective states (i.e. all possible 64 motifs) in the network of regions associated with increased temporal variability (bilateral hippocampi and ACC). After selecting the four regions of interest demonstrating enhanced variability after psilocybin infusion (left and right hippocampus, left and right ACC), the partial correlation between all variables is computed (including also the mean head displacement time series as a partial regressor). After thresholding (with $P < 0.05$, corrected) a series of up to 64 discrete connectivity states are obtained from which the probability distribution can be computed. Finally, from this information, histograms of states (provided here as an illustration) and their corresponding Shannon's entropy (H) can be computed.

DISCUSSION

The novel analyses described in this article provide a considerable amount of new information about how psilocybin affects brain activity. In summary, increased variance in the BOLD signal was observed in the bilateral hippocampi and ACC and the temporal dynamics of these increases corresponded well with the rapid pharmacodynamics of intravenous psilocybin [Carhart-Harris *et al*., 2012, 2013]. Decreased low frequency power and frequency scaling exponent (indicative of a less correlated signal) were observed in higher-level association regions accompanied by an increase in the point process rate at the default mode network. Perhaps the most novel and intriguing aspect of the present analyses was our assessment of dynamical functional connectivity within a simple hippocampal/ACC network. Specifically, a greater diversity of connectivity motifs was observed after psilocybin, reflecting increased entropy in this system's dynamical behavior. Overall these quantities demonstrate an increase in the dynamical repertoire (i.e., new states) in the brain under psilocybin as well as an increase in the rate at which the repertoire is examined.

We first interpret the changes described in the results section from a purely dynamical point of view. The results presented in Figure 1 represent a larger variance in the "mean field activity" of the hippocampus and ACC. This change in variance is the expression of an increased amplitude of the BOLD signal fluctuations in these regions. From a statistical physics point of view, increased signal amplitude implies increased synchronization and so increased correlated activity in the source structures. This is also reflected in the analysis of the repertoire of connectivity states in a hippocampal-ACC network (discussed in Figs. 4 and 5). These two results together reveal an increased variability in the collective repertoire (i.e. a larger number of motifs) of metastable states [Tognoli and Kelso, 2014] within the psychedelic state.

The increased amplitude fluctuations in the hippocampus are particularly intriguing given early depth electroencephalography (EEG) work that recorded similar abnormalities in hippocampal activity after LSD and mescaline [Monroe and Heath, 1961; Schwarz *et al*., 1956]. Similar increases in oscillation amplitude have also been observed in the hippocampus using depth EEG recordings in patients showing nondrug-induced psychotic symptoms [Heath, 1954; Sem-Jacobsen *et al*., 1956] and bursts of high amplitude activity have been seen in human rapid-eye movement (REM) sleep [Cantero *et al*., 2003]. Moreover, other imaging modalities have implicated increased hippocampal activity in psychosis [e.g., Friston *et al*., 1992] and REM sleep [Braun *et al*., 1997; Miyauchi *et al*., 2009]. Given that phenomenological similarities have previously been noted between the psychedelic, psychotic and dream states [Carhart-Harris, 2007; Carhart-Harris and Nutt, 2014], it is intriguing to consider whether altered hippocampal activity may be an important common property of these states.

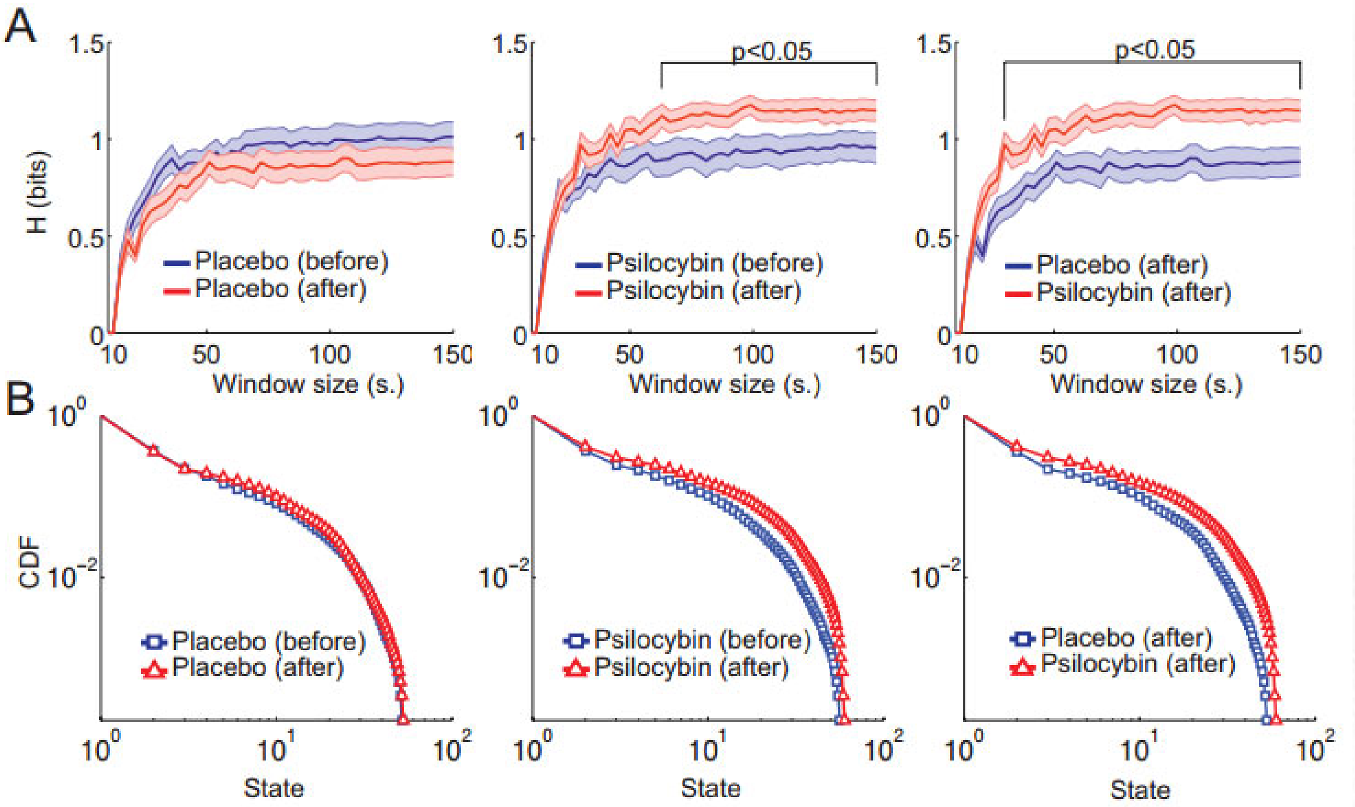

Figure 5. Dynamical functional connectivity entropy increased after psilocybin infusion. **A**) Entropy of connectivity states (H, defined following the procedure outlined in Figure 4 and computed at different time window lengths) are plotted for the comparisons placebo before versus after, psilocybin before versus after and psilocybin after versus placebo after (mean ± SEM). **B**) The probability distributions for the (ranked) dynamical functional connectivity states across all conditions. Histograms were obtained pooling states across subjects and window sizes.

ACC (L)
ACC (R)
Five most frequent states (psilocybin after)
Psilocybin-only states

Figure 5C. First row: five most frequent connectivity states before the infusion of psilocybin. Second row: five most frequent states after the infusion of psilocybin. Third row: states observed only after the infusion of psilocybin, but absent before the infusion and in the placebo condition. In all cases the lines are used to indicate a significant transient functional connectivity between two nodes.

It has long been claimed that the psychedelic (translated "mind-revealing" [Huxley *et al*., 1977]) state is an expanded state of consciousness in which latent psychological material can emerge into consciousness [Cohen, 1967] and novel associations can form. Indeed, this was the original rationale for the use of LSD in psychotherapy [Busch and Johnson, 1950]. It has also been claimed that psychedelics may be able to assist the creative process, for example, by promoting divergent thinking and remote association [Fadiman, 2011]. Thus, the increased repertoire of metastable states observed here with psilocybin may be a mechanism by which these phenomena occur [see also Carhart-Harris *et al.*, 2014].

It was also interesting that under psilocybin, more interhemispheric dynamical correlations were detected in the hippocampal/ACC network (Fig. 5C). Recent electrophysiological work in mice has shown that layer five pyramidal neurons (the primary cellular units implicated in the action of psychedelic drugs [Muthukumaraswamy *et al.*, 2013]) that are sensitive to serotonin 2A receptor mediated excitation (the primary pharmacological process implicated in the action of psychedelics [Muthukumaraswamy *et al.*, 2013]) are disproportionately those pyramidal neurons that project interhemispherically [Avesar and Gulledge, 2012]. Thus, altered interhemispheric communication may be an important component of the mechanism of action of psychedelics.

Concerning the low frequency fluctuations results, these were consistent with our earlier work with MEG in which we observed decreased oscillatory power in neural fields in high-level cortical regions in the 1 to 100 Hz frequency range [Muthukumaraswamy *et al.*, 2013]. In the present analysis, decreased low frequency power in the 0.01 to 0.1 Hz range was found and again, these effects were localized to consistent high-level cortical regions. Low frequency fluctuations in BOLD are known to correlate with neuronal parameters such as fluctuating gamma power and infraslow fluctuations in local field potentials [Pan *et al.*, 2013]. The slower beta band also shows positive correlations with fMRI fluctuations in key DMN regions [Laufs *et al.*, 2003], whereas both alpha and beta apparently inhibit large-scale cortical BOLD coherence [Tagliazucchi *et al.*, 2012b]. Thus, it seems that a primary action of psilocybin, and likely other psychedelics [Riba *et al.*, 2002], is to cause a generalized desynchrony and loss of oscillatory power in higher level cortical regions - likely via serotonin 2A receptor mediated excitation of deep-layer pyramidal neurons in these regions [Muthukumaraswamy *et al.*, 2013]. However, the high amplitude activity detected in the hippocampi and ACC (Fig. 1) suggests that this desynchronizing effect does not generalize to these deeper structures.

The frequency domain result was further examined by a separate analysis of the point-process rate and interval distributions (see Fig. 3). The RSNs which exhibited the most significant changes correspond to higher brain systems such as the DMN, executive control and attention networks and not primary sensory and motor networks. This outcome is consistent with the regional distribution of serotonin 2A receptors [Erritzoe *et al.*, 2009], the receptors implicated in psilocybin's psychedelic action [Vollenweider *et al.*, 1998]. These receptors are concentrated in higher level cortical regions (e.g. the highest distribution in humans is in the PCC [Carhart-Harris *et al.*, 2013; Erritzoe *et al.*, 2009] and are relatively less prevalent in the sensori-motor cortex. That the default mode network has consistently been implicated in the action of psilocybin is also intriguing given its association with self-reflection [Gusnard *et al.*, 2001] and selfhood more generally [Carhart-Harris and Friston, 2010]. It is likely to be relevant therefore that one of the most commonly reported features of an intense psychedelic experience is a compromised sense of selfhood typically described as "ego dissolution" or "ego disintegration" [Carhart-Harris *et al.*, 2014; Klee, 1963; Savage, 1955].

A potential limitation of our study arises from the possibility that psilocybin modifies the coupling between neuronal sources and hemodynamic activity as measured with fMRI (i.e. the hemodynamic response function). However, we note that there exists no evidence for this so far and, on the other hand, there exists ample direct electrophysiological evidence showing that psilocybin modifies brain activity in a way compatible with our findings [Muthukumaraswamy *et al.*, 2013].

Another limitation stems from the limited number of regions included in the definition of dynamical states. This limited number is required to perform an exhaustive counting of all possible states, however, differences in the motifs between conditions (Fig. 5) could arise by direct influence of regions outside the scope of the analysis, which are directly wired to a pair of nodes. Future work should address this limitation and attempt to track those regions to obtain a more complete picture of how dynamical states differ after and before psilocybin infusion.

Finally, it is important to offer some cautionary notes on the analyses documented in this article. Mapping relatively transient dynamical motifs based on resting state fMRI data is a new and exploratory technique. Thus, further work is required to clarify its functional meaning. More specifically, given the Zipf-like behavior of the state distribution probability (Fig. 5B), states that appear rarely (i.e. at the tail of a power law distribution) cannot be trivially tested using the usual statistical significance, i.e. they do not fit easily into the standard frequentist framework of *t*-test statistics, in contrast to well established functional connectivity analyses that represent an average over prolonged periods of time. Thus, further mathematical testing and empirical work is required before we can begin to make confident predictions about the functional relevance of outcomes derived from their application.

ACKNOWLEDGMENTS

The original experiments were performed as part of a broader Beckley-Imperial psychedelic research programme. Authors thank Christian Beckmann for sharing the RSN masks reported in Beckmann *et al*. [2005].

Networks, as efficient representations of complex systems, have appealed to scientists for a long time and now permeate many areas of science, including neuroimaging (Bullmore and Sporns 2009 *Nat. Rev. Neurosci*. 10, 186-198. (doi:10.1038/nrn2618)). Traditionally, the structure of complex networks has been studied through their statistical properties and metrics concerned with node and link properties, e.g. degree-distribution, node centrality and modularity. Here, we study the characteristics of functional brain networks at the mesoscopic level from a novel perspective that highlights the role of inhomogeneities in the fabric of functional connections. This can be done by focusing on the features of a set of topological objects - *homological cycles* - associated with the weighted functional network. We leverage the detected topological information to define the *homological scaffolds*, a new set of objects designed to represent compactly the homological features of the correlation network and simultaneously make their homological properties amenable to networks theoretical methods. As a proof of principle, we apply these tools to compare resting-state functional brain activity in 15 healthy volunteers after intravenous infusion of placebo and psilocybin - the main psychoactive component of magic mushrooms. The results show that the homological structure of the brain's functional patterns undergoes a dramatic change post-psilocybin, characterized by the appearance of many transient structures of low stability and of a small number of persistent ones that are not observed in the case of placebo

1. Motivation

The understanding of global brain organization and its large-scale integration remains a challenge for modern neurosciences. Network theory is an elegant framework to approach these questions, thanks to its simplicity and versatility[1]. Indeed, in recent years, networks have become a prominent tool to analyse and understand neuroimaging data coming from very diverse sources, such as functional magnetic resonance imaging (fMRI), electroencephalography and magnetoencephalography[2,3], also showing potential for clinical applications[4,5].

A natural way of approaching these datasets is to devise a measure of dynamical similarity between the microscopic constituents and interpret it as the strength of the link between those elements. In the case of brain functional activity, this often implies the use of similarity measures such as (partial) correlations or coherence[6-8], which generally yield fully connected, weighted and possibly signed adjacency matrices. Despite the fact that most network metrics can be extended to the weighted case[9-13], the combined effect of complete connectedness and edge weights makes the interpretation of functional networks significantly harder and motivates the widespread use of ad hoc thresholding methods[7,14-18]. However, neglecting weak links incurs the dangers of a trade-off between information completeness and clarity. In fact, it risks overlooking the role that weak links might have, as shown for example in the cases of resting-state dynamics[19,20], cognitive control[21] and correlated network states[22].

In order to overcome these limits, Rubinov & Sporn[13,23,24] recently introduced a set of generalized network and community metrics for functional networks that among others were used to uncover the contrasting dynamics underlying recollection[25] and the physiology of functional hubs[26]. In this paper, we present an alternative route to the analysis of brain functional networks. We focus on the combined structure of connections and weights as captured by the homology of the network. A summary of all the keywords and concepts introduced in this paper can be found in table 1.

Table 1. List of notations.

name	*symbol*	*definition*
graph	G	a graph $G=(V, E)$ is a representation of a set V of nodes i interconnected by edges or links $e_{ij} \in E$; this interaction can be weighted, directional and signed
clique	c	a completely connected subgraph $C=(V', E')$ contained in an undirected and unweighted graph $G=(V, E)(V' \subset V, e_{ij} \in E' \forall i,j \in E')$
k-simplex	σ_k	formally, a convex hull of $k+1$ nodes $[p_0, p_1, \dots, p_k]$, it is used here as a generalization to higher dimensions of the concept of link, e.g. a 2-simplex is a triangle, a 3-simplex a tetrahedron. The faces f of σ_k are obtained as subsets of $[p_0, p_1, \dots, p_k]$
simplicial complex	$\mathscr{K}$	a topological space composed by attaching simplices σ, with two conditions: (i) if $\sigma \in \mathscr{K}$ then all its faces $f \in \mathscr{K}$, and (ii) the intersection of any two σ_i, $\sigma_j \in \mathscr{K}$ is empty or a face of both σ_i and σ_j
clique complex	$\ell(G)$	a simplicial complex built from a graph G by promoting every k-clique $c \subset G$ to a $(k - 1)$-simplex defined by the nodes of c, e.g. a 3-clique becomes a 2-simplex (a full triangle)
kth homology group	$H_k(\mathscr{K})$	a group describing the holes of a simplicial complex $\mathscr{K}$ bounded by k-dimensional boundaries, e.g. H_1 describes two-dimensional cycles bounded by 1-simplices, H_2 describes three-dimensional voids bounded by 2-simplices, etc.
H_k generator	g	an element of the generating set of H_k , a subset of H_k such that all elements can be expressed as combination of generators
homological scaffold	$\mathscr{H}(\mathscr{K})$	a weighted graph constructed from the persistent homology generators of H_1 of a simplicial complex $\mathscr{K}$

2. From networks to topological spaces and homology

Homology is a topological invariant that characterizes a topological space X by counting its holes and their dimensions. By hole, we mean a hollow region bounded by the parts of that space. The dimension of a hole is directly related to the dimension of its boundary. The boundary of a two-dimensional hole is a one-dimensional loop; the three-dimensional inner part of a doughnut, where the filling goes, is bounded by two-dimensional surface; for dimensions higher than 2, it becomes difficult to have a mental representation of a hole, but k-dimensional holes are still bounded by $(k - 1)$ dimensional faces. In our work, we start with a network and from it construct a topological space. We now use figure 1 to show how we proceed and make rigorous what we mean by boundaries and holes.

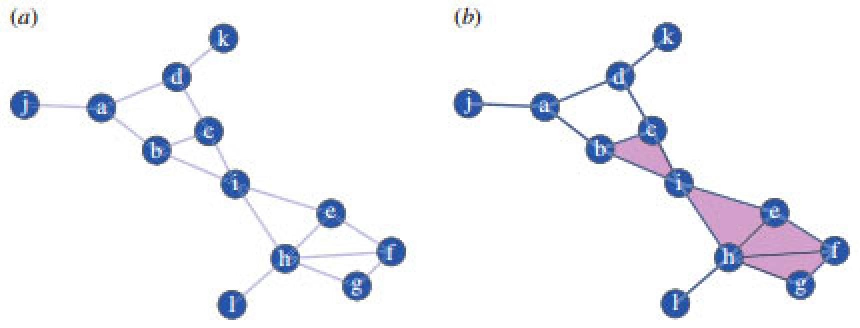

Figure 1. Panels (*a*,*b*) display an unweighted network and its *clique complex*, obtained by promoting cliques to simplices. Simplices can be intuitively thought as higher-dimensional interactions between vertices, e.g. as a simplex the clique (*b*,*c*,*i*) corresponds to a filled triangle and not just its sides. The same principle applies to cliques - thus simplices - of higher order.

In a network like that of figure 1*a*, we want the ring of nodes (*a*,*b*,*c*,*d*) to be a good candidate for a one-dimensional boundary, whereas the other rings of three nodes should not constitute interesting holes. The reason for this choice comes from the formalization of the notion of hole. One way to formalize this is by opposition that is we define what we mean by a dense subnetwork in order to highlight regions of reduced connectivity, i.e. holes. The most natural and conservative definition we can adopt for a dense subnetwork is that of *clique*, a completely connected subgraph[27]. Moreover, cliques have the crucial property, which will be important later, of being nested, i.e. a clique of dimension k (k-clique) contains all the m-cliques defined by its nodes with $m < k$. Using this definition and *filling in* all the maximal cliques, the network in figure 1*a* can be represented as in figure 1*b*: 3-cliques are filled in, becoming tiles, and the only interesting structure left is the square (*a,b,c,d*). It is important at this point to note that a k-clique can be seen as a k - 1 simplex, i.e. as the convex hull of k-points. Our representation of a network can thus be seen as a topological space formed by a finite set of simplices that by construction satisfy the condition that defines the type of topological spaces called abstract simplicial complexes[28]: each element of the space is a simplex, and each of its faces (or subset in the case of cliques) is also a simplex.

This condition is satisfied, because each clique is a simplex, and subsets of cliques are cliques themselves, and the intersection of two cliques is still a clique.

The situation with weighted networks becomes more complicated. In the context of a weighted network, the holes can be thought of as representing regions of reduced connectivity with respect to the surrounding structure.

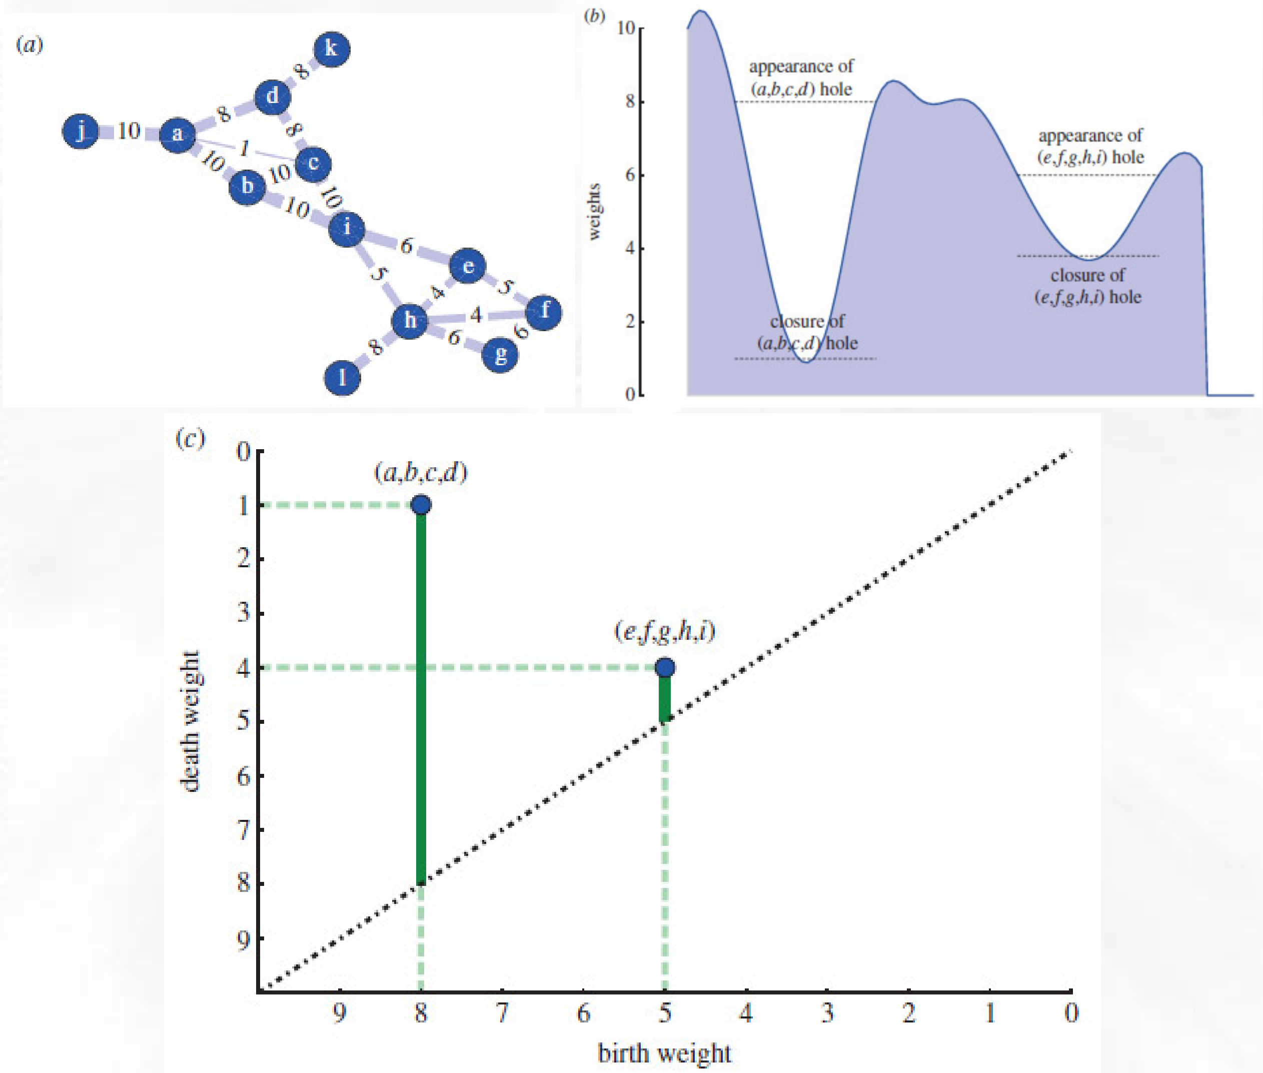

Figure 2. Panels (*a-c*) display a weighted network (*a*), its intuitive representation in terms of a stratigraphy in the weight structure according the weight filtration described in the main text (*b*) and the persistence diagram for H_1 associated with the network shown (*c*). By promoting cliques to simplices, we identify network connectivity with relations between the vertices defining the simplicial complex. By producing a sequence of networks through the filtration, we can study the emergence and relative significance of specific features along the filtration. In this example, the hole defined by (*a,b,c,d*) has a longer persistence (vertical solid green bars) implying that the boundary of the cycle are much heavier than the internal links that eventually close it. The other hole instead has a much shorter persistence, surviving only for one step and is therefore considered less important in the description of the network homological properties. Note that the births and deaths are defined along the sequence of descending edge weights in the network, not in time.

Consider, for example, the case depicted in figure 2*a*: the network is almost the same as figure 1 with the two exceptions that it now has weighted edges and has an additional very weak edge between nodes *a* and *c*. The edges in the cycle [*a*,*b*,*c*,*d*] are all much stronger than the link (*a*,*c*) that closes the hole by making (*a*,*b*,*d*) and (*b*,*c*,*d*) cliques and therefore fills them. The loop (*e*,*f*,*g*,*h*,*i*) has a similar situation, but the difference in edge weights between the links along the cycle and those crossing, is not as large as in the previous case. It would be therefore useful to be able to generalize the approach exposed earlier for binary networks to the case of weighted networks in such a way as to be able to measure the difference between the two cases (*a*,*b*,*c*,*d*) and (*e*,*f*,*g*,*h*,*i*). As shown by figure 2*b*, this problem can be intuitively thought of as a stratigraphy in the link-weight fabric of the network, where the aim is to detect the holes, measure their depth and when they appear as we scan across the weights' range.

From figure 2*b*, it becomes clear that the added value of this method over conventional network techniques lies in its capability to describe mesoscopic patterns that coexist over different intensity scales, and hence to complement the information about the community structure of brain functional networks. A way to quantify the relevance of holes is given by *persistent homology*. We describe it and its application to the case of weighted networks in full detail in §3.

3. A persistent homology of weighted networks

The method that we adopt was introduced in references[29,30] and relies on an extension of the metrical persistent homology theory originally introduced by references[31,32]. Technical details about the theory of persistent homology and how the computation is performed can be found in the works of Carlsson, Zomorodian and Edelsbrunner[28,31-35]. Persistent homology is a recent technique in computational topology developed for shape recognition and the analysis of high dimensional datasets[36,37]. It has been used in very diverse fields, ranging from biology[38,39] and sensor network coverage[40] to cosmology[41]. Similar approaches to brain data[42,43], collaboration data[44] and network structure[45] also exist. The central idea is the construction of a sequence of successive approximations of the original dataset seen as a topological space X. This sequence of topological spaces $X_0, X_1, \ldots, X_N, = X$ is such that $X_i \subseteq X_j$ whenever $i<j$ and is called the *filtration*. Choosing how to construct a filtration from the data is equivalent to choosing the type of goggles one wears to analyse the data.

In our case, we sort the edge weights in descending order and use the ranks as indices for the subspaces. More specifically, denote by $\Omega=(V, E, \omega)$ the functional network with vertices V, edges E and weights $\bar{\omega}: E \rightarrow \mathbb{R}$. We then consider the family of binary graphs $G_\omega=(V, E_\omega)$*, where an edge* $e \in E$ *is also included in* G_ω *if its weight* ω_e *is larger than* ω $(e \in E_\omega \Leftrightarrow \bar{\omega}(e) \geq \omega)$.

To each of the $G_{\omega'}$, we associate its *clique*, or *flag complex* $\mathcal{K}_{\omega'}$, that is the simplicial complex that contains the k-simplex $[n_0, n_1, n_2, \ldots n_{k-1}]$ whenever the nodes $n_0, n_1, n_2, \ldots n_{k-1}$ define a clique in G_ω[27]. As subsets of cliques and intersections of cliques are cliques themselves, as we pointed out in §2, our clique complex is thus a particular case of a simplicial complex.

The family of complexes $\{\mathcal{K}_\omega\}$ defines a filtration, because we have $\mathcal{K}_\omega \subseteq \mathcal{K}'_\omega$ for $\omega > \omega'$. At each step, the simplices in $\mathcal{K}_\omega$ inherit their configuration from the underlying network structure and, because the filtration swipes across all weight scales in descending order, the holes among these units constitute mesoscopic regions of reduced functional connectivity.

Moreover, this approach also highlights how network properties evolve along the filtration, providing insights about where and when lower connectivity regions emerge. This information is available, because it is possible to keep track of each k-dimensional cycle in the homology group H_k. A generator uniquely identifies a hole by its constituting elements at each step of the filtration process. The importance of a hole is encoded in the form of 'time-stamps' recording its birth β_g and death δ_g along the filtration $\{\mathcal{K}_\omega\}$[31]. These two time-stamps can be combined to define the *persistence* $\pi_g = \delta_g - \beta_g$ of a hole, which gives a notion of its importance in terms of it lifespan. Continuing the analogy with stratigraphy, β_g and δ_g correspond, respectively, to the top and the bottom of a hole and π_g would be its depth. As we said above, a generator g_i^k, or hole, of the kth homology group H_k is identified by its birth and death along the filtration. Therefore, g_i^k is described by the point $(\beta_g, \delta_g) \in \mathbb{R}^2$. A standard way to summarize the information about the whole kth persistent homology group is then to consider the diagram obtained plotting the points corresponding to the set of generators. The (multi)set $\{(\beta_g, \delta_g)\}$ is called the persistence diagram of H_k. In figure 2*c*, we show the persistence diagram for the network shown in figure 2*a* for H_1. Axes are labelled by weights in decreasing order. It is easy to check that the coordinates correspond exactly to the appearance and disappearance of generators. The green vertical bars highlight the persistence of a generator along the filtration. The further a point is from the diagonal (vertically), the more persistent the generator is. In §4, we introduce two objects, the persistence and the frequency homological scaffolds, designed to summarize the topological information about the system.

4. Homological scaffolds

Once one has calculated the generators $\{g_i^k\}_i$ of the kth persistent homology group H_k, the corresponding persistence diagram contains a wealth of information that can be used, for example, to highlight differences between two datasets. It would be instructive to obtain a synthetic description of the uncovered topological features in order to interpret the observed differences in terms of the microscopic components at least for low dimensions k. Here, we present a scheme to obtain such a description by using the information associated with the generators during the filtration process. As each generator,g_i^k is associated with a whole equivalence class, rather than to a single chain of simplices, we need to choose a representative for each class, we use the representative that is returned by the *javaplex* implementation[46] of the persistent homology algorithm[47]. For the sake of simplicity in the following, we use the same symbol g_i^k to refer to a generator and its representative cycle.

We exploit this to define two new objects, the persistence and the frequency *homological scaffolds* $\mathscr{H}^p_G$ and $\mathscr{H}^f_G$ of a graph G. The *persistence homological scaffold* is the network composed of all the cycle paths corresponding to generators weighted by their persistence. If an edge e belongs to multiple cycles g_0, g_1, ..., g_s, its weight is defined as the sum of the generators' persistence:

$$\omega_e^\pi = \sum_{g_i | e \in g_i} \pi_{g_i}. \tag{4.1}$$

Similarly, we define the *frequency homological scaffold* $\mathscr{H}^f_G$ as the network composed of all the cycle paths corresponding to generators, where this time, an edge e is weighted by the number of different cycles it belongs to

$$\omega_e^f = \sum_{g_i} 1_{e \in g_i}, \tag{4.2}$$

where $1_{e \in g_i}$ is the indicator function for the set of edges composing g_i. By definition, the two scaffolds have the same edge set, although differently weighted.

The construction of these two scaffolds therefore highlights the role of links which are part of many and/or long persistence cycles, isolating the different roles of edges within the functional connectivity network. The persistence scaffolds encodes the overall persistence of a link through the filtration process: the weight in the persistence scaffold of a link belonging to a certain set of generators is equal to the sum of the persistence of those cycles. The frequency scaffold instead highlights the number of cycles to which a link belongs, thus giving another measure of the importance of that edge during the filtration. The combined information given by the two scaffolds then enables us to decipher the nature of the role different links have regarding the homological properties of the system. A large total persistence for a link in the persistence scaffold implies that the local structure around that link is very weak when compared with the weight of the link, highlighting the link as a locally strong bridge. We remark that the definition of scaffolds we gave depends on the choice of a specific basis of the homology group, and the choice of a consistent basis is an open problem in itself, therefore the scaffolds are not topological invariants. Moreover, it is possible for an edge to be added to a cycle shortly after the cycle's birth in such a way that it creates a triangle with the two edges composing the cycle. In this way, the new edge would be part of the shortest cycle, but the scaffold persistence value would be misattributed to the two other edges. This can be checked, for example, by monitoring the clustering coefficient of the cycle's subgraph as edges are added to it. We checked for this effect and found that in over 80% of the cases the edges do not create triangles that would imply the error, but instead new cycles are created, whose contribution to the scaffold is then accounted for by the new cycle. Finally, we note also that, when a new triangle inside the cycle is created, the two choices of generator differ for a path through a third strongly connected node, owing to the properties of boundary operators. Despite this ambiguity, we show in the following that they can be useful to gain an understanding of what the topological differences detected by the persistent homology actually mean in terms of the system under study.

5. Results from fMRI networks

We start from the processed fMRI time series (see Methods for details). The linear correlations between regional time series were calculated after covarying out the variance owing to all other regions and the residual motion variance represented by the 24 rigid motion parameters obtained from the preprocessing, yielding a partial-correlation matrix χ^α for each subject. The matrices χ^α were then analysed with the algorithm described in the previous sections. We calculated the generators g_i^1 of the first homological group H_1 along the filtration. As mentioned before, each of these generators identifies a lack of mesoscopic connectivity in the form of a one-dimensional cycle and can be represented in a persistence diagram. We aggregate together the persistence diagrams of subjects belonging to each group and compute an associated persistence probability density (figure 3). These probability density functions constitute the statistical signature of the groups' H_1 features.

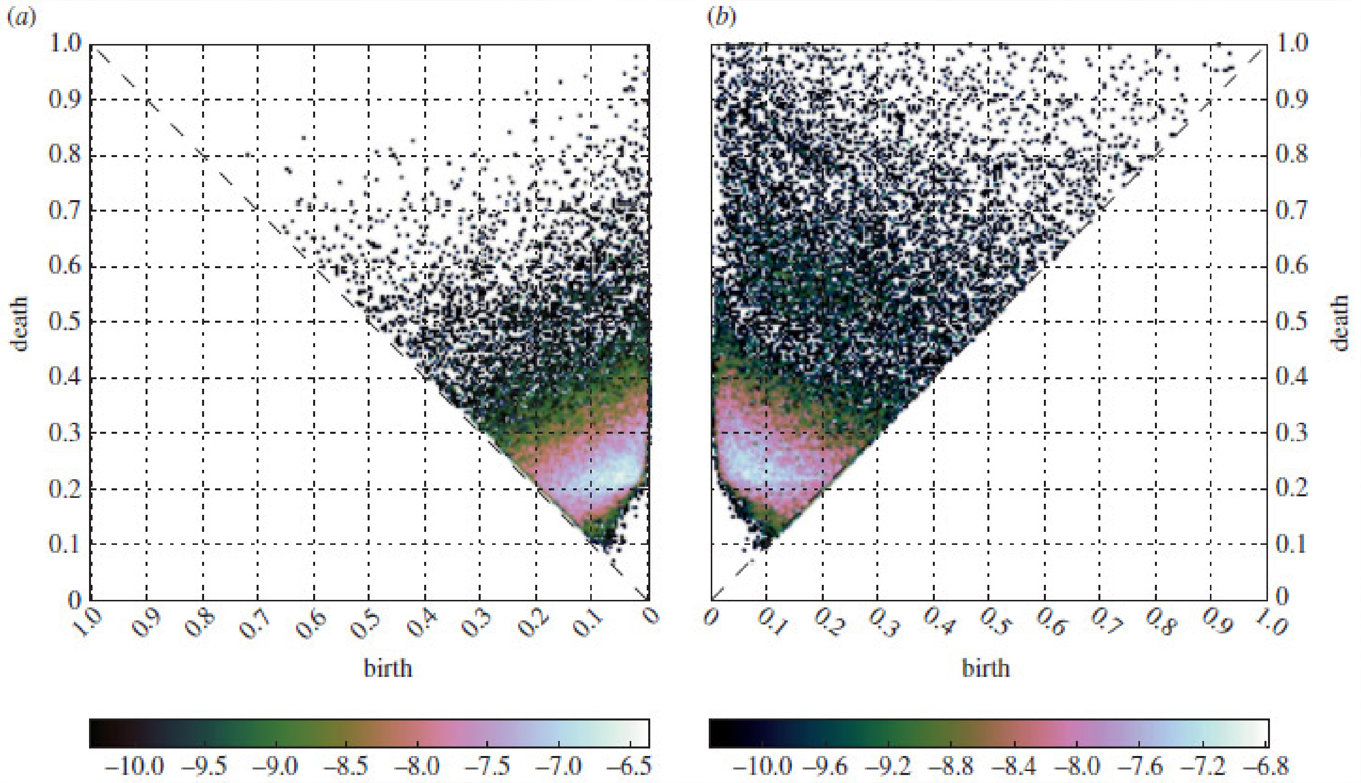

Figure 3. Probability densities for the H_1 generators. Panel (*a*) reports the (log-)probability density for the placebo group, whereas panel (*b*) refers to the psilocybin group. The placebo displays a uniform broad distribution of values for the births - deaths of H_1 generators, whereas the plot for the psilocybin condition is very peaked at small values with a fatter tail. These heterogeneities are evident also in the persistence distribution and find explanation in the different functional integration schemes in placebo and drugged brains.

We find that, although the number of cycles in the groups are comparable, the two probability densities strongly differ (Kolmogorov-Smirnov statistics: 0.22, *p*-value less than 10^{-10}).

The placebo group displays generators appearing and persisting over a limited interval of the filtration. On the contrary, most of the generators for the psilocybin group are situated in a well-defined peak at small birth indices, indicating a shorter average cycle persistence. However, the psilocybin distribution is also endowed with a longer tail implying the existence of a few cycles that are longer-lived compared with the placebo condition and that influences the weight distribution of the psilocybin persistence scaffold. The difference in behaviour of the two groups is made explicit when looking at the probability distribution functions for the persistence and the birth of generators (figure 4), which are both found to be significantly different (Kolmogorov-Smirnov statistics: 0.13, p-value $< 10^{-30}$ for persistence and Kolmogorov-Smirnov statistics: 0.14, p-value $< 10^{-35}$ for births). In order to better interpret and understand the differences between the two groups, we use the two secondary networks described in §4, $\mathscr{H}^{f}_{\text{Pla}}$ and $\mathscr{H}^{p}_{\text{Pla}}$ for the placebo group and $\mathscr{H}^{f}_{\text{Psi}}$ and $\mathscr{H}^{p}_{\text{Psi}}$ for the psilocybin group. The weight of the edges in these secondary networks is proportional to the total number of cycles an edge is part of, and the total persistence of those cycles, respectively. They complement the information given by the persistence density distribution, where the focus is on the entire cycle's behaviour, with information on single links. In fact, individual edges belonging to many and long persistence cycles represent functionally stable 'hub' links. As with the persistence density distribution, the scaffolds are obtained at a group level by aggregating the information about all subjects in each group. These networks are slightly sparser than the original complete χ^{α} networks

$$\rho(\mathscr{H}^{f,p}_{\text{pla}}) = \frac{2m(\mathscr{H}^{p}_{\text{pla}})}{n(n-1)} = 0.92 \tag{5.1}$$

and

$$\rho(\mathscr{H}^{f,p}_{\text{Psi}}) = \frac{2m(\mathscr{H}^{p}_{\text{Psi}})}{n(n-1)} = 0.91 \tag{5.2}$$

and have comparable densities. A first difference between the two groups becomes evident when we look at the distributions for the edge weights (figure 5*a*). In particular, the weights of $\mathscr{H}^{p}_{\text{Pla}}$ display a cut-off for large weights, whereas the weights of $\mathscr{H}^{p}_{\text{Psi}}$ have a broader tail (Kolmogorov-Smirnov statistics: 0.06, p-value $< 10^{-20}$; figure 5*a*). Interestingly, the frequency scaffold weights probability density functions cannot be distinguished from each other figure 5*a* (inset) (Kolmogorov- Smirnov statistics: 0.008, p-value = 0.72). Taken together, these two results imply that while edges statistically belong to the same number of cycles, in the psilocybin scaffold, there exist very strong, persistent links.

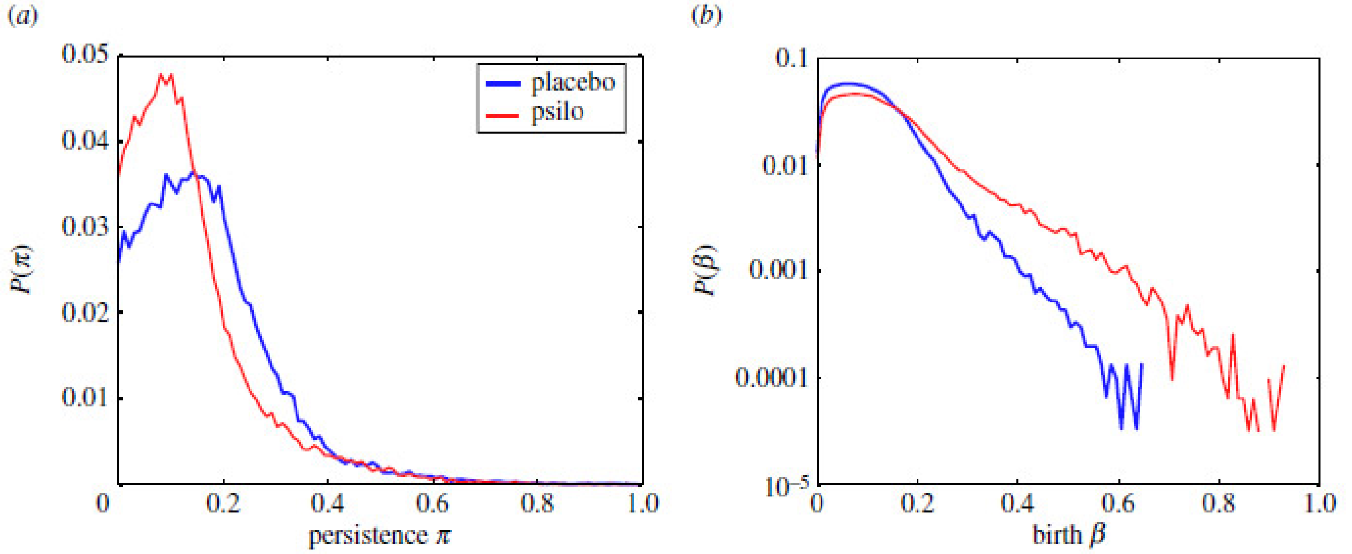

Figure 4. Comparison of persistence π and birth β distributions. Panel (*a*) reports the H_1 generators' persistence distributions for the placebo group (blue line) and psilocybin group (red line). Panel (*b*) reports the distributions of births with the same colour scheme. It is very easy to see that the generators in the psilocybin condition have persistence peaked at shorter values and a wider range of birth times when compared with the placebo condition.

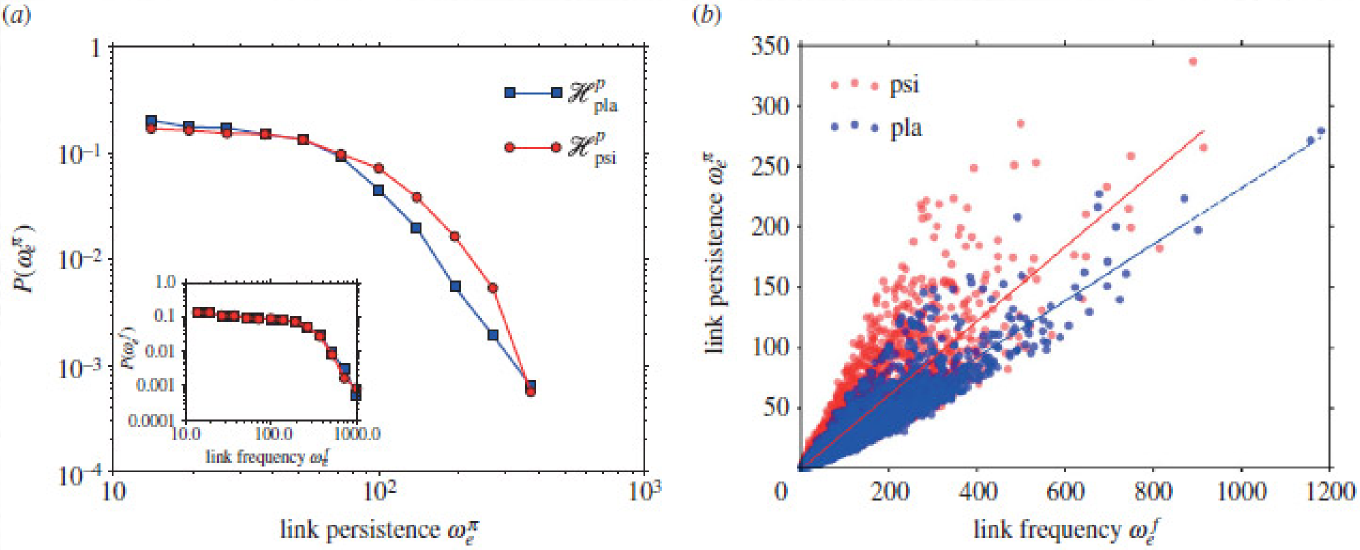

Figure 5. Statistical features of group homological scaffolds. Panel (*a*) reports the (log-binned) probability distributions for the edge weights in the persistence homological scaffolds (main plot) and the frequency homological scaffolds (inset). While the weights in the frequency scaffold are not significantly different, the weight distributions for the persistence scaffold display clearly a broader tail. Panel (*b*) shows instead the scatter plot of the edge frequency versus total persistence. In both cases, there is a clear linear relationship between the two, with a large slope in the psilocybin case. Moreover, the psilocybin scaffold has a larger spread in the frequency and total persistence of individual edges, hinting to a different local functional structure within the functional network of the drugged brains.

The difference between the two sets of homological scaffolds for the two groups becomes even more evident when one compares the weights between the frequency and persistence scaffolds of the same group. Figure 5*b* is a scatter plot of between the weights of edges from both scaffolds for the two groups. The placebo group has a linear relationship between the two quantities meaning that edges that are persistent also belongs to many cycles (R^2 = 0.95, slope = 0.23). Although the linear relationship is still a reasonable fit for the psilocybin group (R^2 = 0.9, slope = 0.3), the data in this case display a larger dispersion. In particular, it shows that edges in $\mathscr{H}^{f,p}{}_{psi}$ can be much more persistent/longer-lived than in $\mathscr{H}^{f,p}{}_{pla}$ but still appear in the same number of cycles, i.e. the frequency of a link is not predictive of its persistence or simply put: some connections are much more persistent in the psychedelic state. Moreover, the slopes of linear fits of the two clouds are statistically different (p-value < 10^{-20}, n_{pla}=13 200 and n_{psi}=13 275[48]) pointing to a starkly different local functional structure in the two conditions.

The results from the persistent homology analysis and the insights provided by the homological scaffolds imply that although the mesoscopic structures, i.e. cycles, in the psilocybin condition are less stable than in the placebo group, their constituent edges are more stable.

6. Discussion

In this paper, we first described a variation of persistent homology that allows us to deal with weighted and signed networks. We then introduced two new objects, the homological scaffolds, to go beyond the picture given by persistent homology to represent and summarize information about individual links. The homological scaffolds represent a new measure of topological importance of edges in the original system in terms of how frequently they are part of the generators of the persistent homology groups and how persistent are the generators to which they belong to. We applied this method to an fMRI dataset comprising a group of subjects injected with a placebo and another injected with psilocybin.

By focusing on the second homology group H_1, we found that the stability of mesoscopic association cycles is reduced by the action of psilocybin, as shown by the difference in the probability density function of the generators of H_1 (figure 3).

It is here that the importance of the insight given by the homological scaffolds in the persistent homology procedure becomes apparent. A simple reading of this result would be that the effect of psilocybin is to relax the constraints on brain function, ascribing cognition a more flexible quality, but when looking at the edge level, the picture becomes more complex. The analysis of the homological scaffolds reveals the existence of a set of edges that are predominant in terms of their persistence although they are statistically part of the same number of cycles in the two conditions (figure 5). In other words, these functional connections support cycles that are especially stable and are only present in the psychedelic state. This further implies that the brain does not simply become a random system after psilocybin injection, but instead retains some organizational features, albeit different from the normal state, as suggested by the first part of the analysis. Further work is required to identify the exact functional significance of these edges. Nonetheless, it is interesting to look at the community structure of the persistence homological scaffolds in figure 6. The two pictures are simplified cartoons of the placebo (figure 6*a*) and psilocybin (figure 6*b*) scaffolds. In figure 6*a,b*, the nodes are organized and coloured according to their community membership in the placebo scaffold (obtained with the Louvain algorithm for maximal modularity and resolution 1[50]). This is done in order to highlight the striking difference in connectivity structure in the two cases.When considering the edges in the tail of the distribution, weight greater than or equal to 80, in figure 5*a*, only 29 of the 374 edges present in the truncated psilocybin scaffold are shared with the truncated placebo scaffold (165 edges). Of these 374 edges, 217 are between placebo communities and are observed to mostly connect cortical regions. This supports our idea that psilocybin disrupts the normal organization of the brain with the emergence of strong, topologically long-range functional connections that are not present in a normal state.

The two key results of the analysis of the homological scaffolds can therefore be summarized as follows (i) there is an increased integration between cortical regions in the psilocybin state and (ii) this integration is supported by a persistent scaffold of a set of edges that support cross modular connectivity probably as a result of the stimulation of the 5-HT_{2A} receptors in the cortex[51].

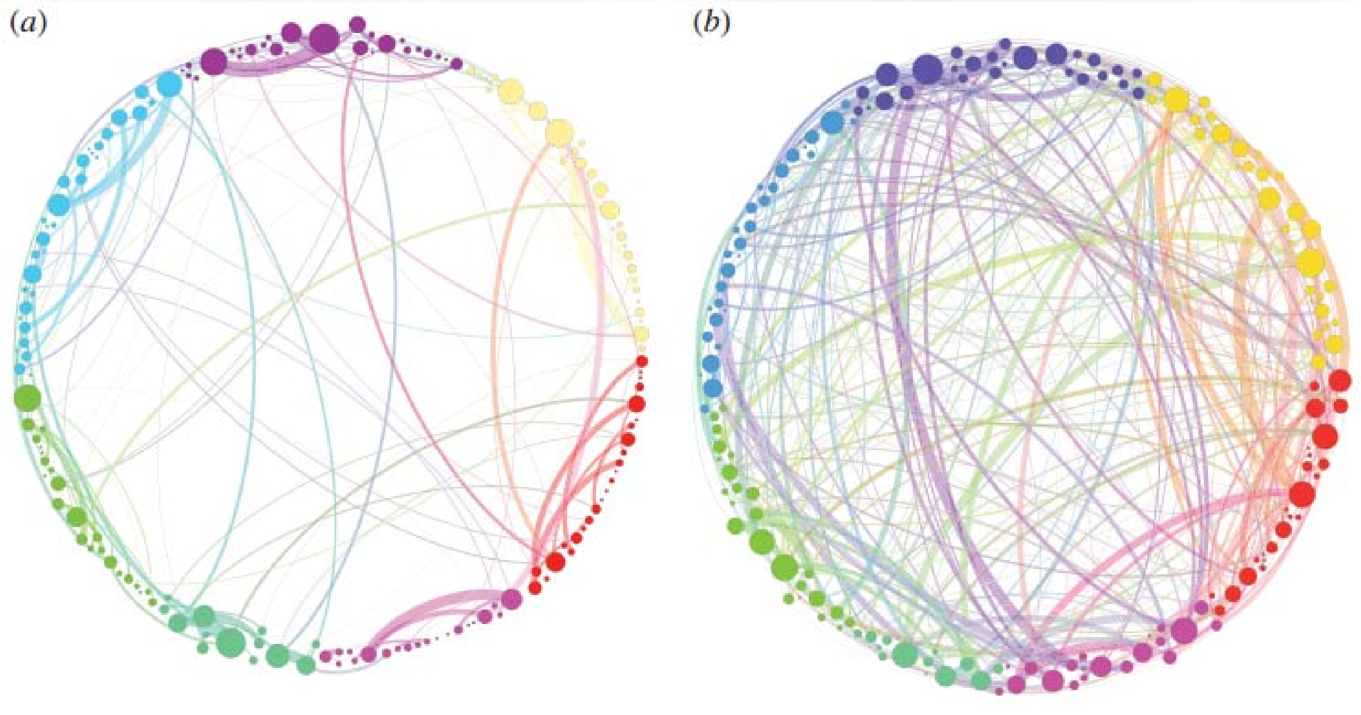

Figure 6. Simplified visualization of the persistence homological scaffolds. The persistence homological scaffolds $\mathscr{H}^{p}_{\mathrm{pla}}$ (*a*) and $\mathscr{H}^{p}_{\mathrm{psi}}$ (*b*) are shown for comparison. For ease of visualization, only the links heavier than 80 (the weight at which the distributions in figure 5*a* bifurcate) are shown. This value is slightly smaller than the bifurcation point of the weights distributions in figure 5*a*. In both networks, colours represent communities obtained by modularity[49] optimization on the placebo persistence scaffold using the Louvain method[50] and are used to show the departure of the psilocybin connectivity structure from the placebo baseline. The width of the links is proportional to their weight and the size of the nodes is proportional to their strength. Note that the proportion of heavy links between communities is much higher (and very different) in the psilocybin group, suggesting greater integration. A labelled version of the two scaffolds is available as GEXF graph files as the electronic supplementary material.

We can speculate on the implications of such an organization. One possible by-product of this greater communication across the whole brain is the phenomenon of synaesthesia which is often reported in conjunction with the psychedelic state. Synaesthesia is described as an inducer-concurrent pairing, where the inducer could be a grapheme or a visual stimulus that generates a secondary sensory output - like a colour for example. Drug-induced synaesthesia often leads to chain of associations, pointing to dynamic causes rather than fixed structural ones as may be the case for acquired synaesthesia[52]. Broadly consistent with this, it has been reported that subjects under the influence of psilocybin have objectively worse colour perception performance despite subjectively intensified colour experience[53].

To summarize, we presented a new method to analyse fully connected, weighted and signed networks and applied it to a unique fMRI dataset of subjects under the influence of mushrooms. We find that the psychedelic state is associated with a less constrained and more intercommunicative mode of brain function, which is consistent with descriptions of the nature of consciousness in the psychedelic state.

7. Methods

7.1. Dataset

A pharmacological MRI dataset of 15 healthy controls was used for a proof-of-principle test of the methodology[54]. Each subject was scanned on two separate occasions, 14 days apart. Each scan consisted of a structural MRI image (T1-weighted), followed by a 12 min eyes-close resting-state blood oxygen-level-dependent (BOLD) fMRI scan which lasted for 12 min. Placebo (10 ml saline, intravenous injection) was given on one occasion and psilocybin (2 mg dissolved in 10 ml saline) on the other. Injections were given manually by a study doctor situated within the scanning suite. Injections began exactly 6 min after the start of the 12-min scans, and continued for 60 s.

7.1.1. Scanning parameters

The BOLD fMRI data were acquired using standard gradient-echo EPI sequences, reported in detail in reference[54]. The volume repetition time was 3000 ms, resulting in a total of 240 volumes acquired during each 12 min resting-state scan (120 pre- and 120 post-injection of placebo/psilocybin).

7.1.2. Image pre-processing

fMRI images were corrected for subject motion within individual resting-state acquisitions, by registering all volumes of the functional data to the middle volume of the acquisition using the FMRIB linear registration motion correction tool, generating a six-dimension parameter time course[55]. Recent work demonstrates that the six parameter motion model is insufficient to correct for motion-induced artefact within functional data, instead a Volterra expansion of these parameters to form a 24 parameter model is favoured as a trade-off between artefact correction and lost degrees of freedom as a result of regressing motion away from functional time courses[56]. fMRI data were pre-processed according to standard protocols using a high-pass filter with a cut-off of 300 s.

Structural MRI images were segmented into n = 194 cortical and subcortical regions, including white matter cerebrospinal fluid (CSF) compartments, using FREESURFER (http://surfer.nmr. mgh.harvard.edu/), according to the Destrieux anatomical atlas[57]. In order to extract mean-functional time courses from the BOLD fMRI, segmented T1 images were registered to the middle volume of the motion-corrected fMRI data, using boundary-based registration[58], once in functional space mean time-courses were extracted for each of the n = 194 regions in native fMRI space.

7.1.3. Functional connectivity

For each of the 194 regions, alongside the 24 parameter motion model time courses, partial correlations were calculated between all couples of time courses (i,j), non-neural time courses (CSF, white matter and motion) were discarded from the resulting functional connectivity matrices, resulting in a 169 region cortical/subcortical functional connectivity corrected for motion and additional non-neural signals (white matter/CSF).

7.2. Persistent homology computation

For each subject in the two groups, we have a set of persistence diagrams relative to the persistent homology groups H_n. In this paper, we use the H_1 persistence diagrams of each group to construct the corresponding persistence probability densities for H_1 cycles.

Filtrations were obtained from the raw partial-correlation matrices through the PYTHON package *Holes* and fed to *javaplex*[46] via a Jython subroutine in order to extract the persistence intervals and the representative cycles. The details of the implementation can be found in reference[30], and the software is available at Holes[59].

Funding statement. G.P. and F.V. are supported by the TOPDRIM project supported by the Future and Emerging Technologies programme of the European Commission under Contract IST-318121. I.D. P.E. and F.T. are supported by a PET methodology programme grant from the Medical Research Council UK (ref no. G1100809/1). Abstract

Growing evidence from the dynamical analysis of functional neuroimaging data suggests that brain function can be understood as the exploration of a repertoire of metastable connectivity patterns ('functional brain networks'), which potentially underlie different mental processes.
The present study characterizes how the brain's dynamical exploration of resting-state networks is rapidly modulated by intravenous infusion of psilocybin, a tryptamine psychedelic found in "magic mushrooms". We employed a data-driven approach to characterize recurrent functional connectivity patterns by focusing on the leading eigenvector of BOLD phase coherence at single-TR resolution. Recurrent BOLD phase-locking patterns (PL states) were assessed and statistically compared pre- and post-infusion of psilocybin in terms of their probability of occurrence and transition profiles. Results were validated using a placebo session.
Recurrent BOLD PL states revealed high spatial overlap with canonical resting-state networks. Notably, a PL state forming a frontoparietal subsystem was strongly destabilized after psilocybin injection, with a concomitant increase in the probability of occurrence of another PL state characterized by global BOLD phase coherence. These findings provide evidence of network-specific neuromodulation by psilocybin and represent one of the first attempts at bridging molecular pharmacodynamics and whole-brain network dynamics.

1. Introduction

Brain dynamics can be understood as the exploration of activity configurations over both space and time (Tononi and Edelman, 1998; Watanabe *et al*., 2014; Cabral *et al*., 2017b; Gu *et al*., 2018). This exploration may be defined in terms of trajectories within a fixed repertoire of metastable activity patterns, which potentially underlie different brain processes. Indeed, a robust repertoire of large-scale functional networks has been consistently detected across individuals and neuroimaging modalities, not only during task performance but also during rest (Damoiseaux *et al*., 2006; De Luca *et al*., 2006; Mantini *et al*., 2007; Seeley *et al*., 2007; Musso *et al*., 2010; Brookes *et al*., 2011; Yeo *et al*., 2011; Hipp *et al*., 2012), indicating that brain function involves the coordinated integration of information over a repertoire of spatially distributed networks of specialized brain areas (Varela, 1979; Bressler and Menon, 2010; Menon, 2011; Cavanna *et al*., 2017; Lord *et al*., 2017). While the mechanisms driving the spontaneous formation and dissolution of functional networks remain under debate (Cabral *et al*., 2017a), brain function has recently been explored in terms of transitions between recurrent states of functional connectivity (Hansen *et al*., 2015; Cabral *et al*., 2017a; Cavanna *et al*., 2017; Tewarie *et al*., 2019). Although the functional relevance of these explorative dynamics during rest remains unclear (Christoff *et al*., 2016), recent evidence suggests that transitions between brain states are organized in a hierarchical manner (Vidaurre *et al*., 2017) and relate to cognitive function (Cabral *et al*., 2017b).

Novel insights into the neurobiological correlates of functional network states and their relationship to behavior in both health and disease can be gained by understanding how specific psychoactive compounds modulate the relative stability of functional networks over time, as well as the transitions between them. Toward this aim, the present study investigates how psilocybin (4-phosphoryloxy-N,Ndimethyltryptamine) changes the exploration of the brain's dynamical repertoire. Psilocybin is a prodrug of psilocin (4-OH-*N,N*-dimethyltrayptamine) - a psychoactive ingredient found in so-called "magic mushrooms" and classical tryptamine 'psychedelic'. The subjective effects of psilocybin/psilocin include broadly unconstrained perception and cognition, hyper-associative cognition and, at higher doses, a breakdown in the perception of time, space and selfhood (Griffiths *et al*., 2006; Carhart-Harris *et al*., 2014). Psilocybin provides a promising experimental framework for linking molecular pharmacodynamics to changes in the brain's dynamical repertoire because its potent psychoactive effects are selectively due to its agonist activity at the serotonin 2A (5-HT$_{2A}$) receptor (McKenna *et al.*, 1990; Vollenweider *et al.*, 1998; Passie *et al.*, 2002; González-Maeso *et al.*, 2007) - see Beliveau *et al.* (2017) for the highest resolution *in vivo* mapping of 5-HT$_{2A}$ receptor densities in the human brain. Furthermore, investigating how psilocybin modulates the exploration of functional network states over time may help better understand the functional mechanisms underlying the recently demonstrated therapeutic potential of psilocybin (and other indolealkylamines) for disorders including depression, anxiety and addiction (McKenna *et al.*, 1990; Griffiths *et al.*, 2006; Grob *et al.*, 2011; Meltzer *et al.*, 2012; Johnson *et al.*, 2014; Carhart-Harris *et al.*, 2016).

The first fMRI investigation of psilocybin's effects on the human brain consisted of a task-free paradigm in which healthy subjects were intravenously injected with the compound inside the scanner (or a placebo, at least 1 week apart) to characterize changes in brain activity under the influence of the drug (Carhart-Harris *et al.*, 2012). The first dynamical analysis of this dataset found increased variance of intra-network synchrony over time for a number of canonical resting-state networks under psilocybin (Carhart-Harris *et al.*, 2014). Somewhat consistently, a subsequent analysis of this same fMRI dataset using sliding-window correlations within a specific network of four brain regions (comprising the bilateral hippocampus and anterior cingulate cortex) revealed both a larger repertoire of functional motifs under psilocybin as well as greater entropy of the motif sequence (Tagliazucchi *et al.*, 2014). Another experiment using MEG revealed increased Lempel-Ziv complexity -a measure of neural signal diversity calculated at the single-channel level (Lempel and Ziv, 1976)- following psilocybin administration relative to placebo (Schartner *et al.*, 2017). However, it is important to clarify that an increase in local complexity does not necessarily imply higher randomness at the larger scale. This seeming paradox can be explained by the findings in a recent study (Atasoy *et al.*, 2018), where higher coherence - expressed as increased power and energy of connectome harmonic brain states under psilocybin - was accompanied by an enlarged repertoire of brain states, leading to higher spatial and temporal variability. Additionally, other works have shown that the serotonergic psychedelics psilocybin and LSD induce an alternative type of functional integration characterized by greater global integration (Petri *et al.*, 2014; Roseman *et al.*, 2014; Tagliazucchi *et al.*, 2016). However, despite the consistent advancements, how psilocybin modulates the relative occupancy of specific functional networks over time and how it relates to the subjective psychedelic experience has not yet been explored.

Recently, a number of methodological approaches have been proposed to analyze BOLD connectivity dynamics at high temporal resolution (i.e., single volume/TR), focusing either on BOLD co-activation patterns (Tagliazucchi *et al.*, 2012; Liu and Duyn, 2013; Karahanoglu and Van De Ville, 2015), or on BOLD phase coherence patterns (Glerean *et al.*, 2012; Hellyer *et al.*, 2015; Cabral *et al.*, 2017b). While co-activation approaches (in their variant forms) are only sensitive to simultaneity in the data, phase coherence techniques can, by definition, capture temporally delayed relationships, which may be more sensitive to capture the ultra-slow oscillatory processes governing the formation of resting-state networks - as proposed by recent experimental and computational studies (Deco *et al.*, 2009; Cabral *et al.*, 2014a, 2017a; Ponce-Alvarez *et al.*, 2015; Deco and Kringelbach, 2016; Gutierrez-Barragan *et al.*, 2018; Roberts *et al.*, 2019).

To identify recurrent patterns of BOLD phase coherence across subjects and quantify differences in the exploration of the repertoire of functional networks in the current dataset, we employed a recently developed data-driven approach, the Leading Eigenvector Dynamics Analysis (LEiDA), which captures instantaneous phase-locking patterns with reduced dimensionality by considering only the relative phase of BOLD signals (i.e., how all BOLD phases project into their leading eigenvector at each discrete time point) (Cabral *et al.*, 2017b; Figueroa *et al.*, 2019). LEiDA appears as a valuable step in the search for functional network recurrences in dynamical analysis because the reduced dimensionality (from an NxN matrix to a 1xN vector) allows for better convergence of the clustering algorithm, revealing robust BOLD phase-locking patterns that consistently reoccur across fMRI scans for different subjects. However, despite returning meaningful functional subsystems in previous studies (Cabral *et al.*, 2017b; Figueroa *et al.*, 2019), the recurrent patterns identified by LEiDA have not yet been qualitatively compared to canonical resting-state networks (Damoiseaux *et al.*, 2006; Yeo *et al.*, 2011).

In the current work, we therefore employed the LEiDA approach to identify recurrent BOLD phase-locking patterns (PL states) and quantified differences in their probability of occurrence and transition profiles before and after the infusion of psilocybin, while subjects were inside the MRI scanner. The validity of the results was subsequently verified using the placebo dataset, and the repertoire of PL patterns returned by LEiDA was compared to well-established resting-state networks described in the literature.

2. Methods

The full description of the participants, protocol and acquisition is provided in Carhart-Harris *et al*. (2012). Only a brief description is included below.

3. Participants

Employing rigorous standards for data quality, namely minimal motion during the scan, at least 21 years of age, no personal or family history of a major psychiatric disorder, no substance dependence, no cardiovascular disease, and no history of adverse response to a psychedelic drug yielded datasets for nine participants. All subjects had used psilocybin at least once before, but not within 6 weeks of the study.

4. Ethics statement

The study was approved by a National Health Service research ethics committee and all participants gave informed consent to participate in the study.

5. Experimental protocol

All subjects underwent two 12 min eyes-closed resting state fMRI scans over separate sessions, at least 7 days apart. In each session, subjects were injected intravenously with either psilocybin (2 mg dissolved in 10 ml saline, 60 s intravenous injection) or a placebo (10 ml saline, 60 s intravenous injection) in a counterbalanced design (see Fig. 2 for an illustration of the scanning paradigm). Injections were given manually by a Physician within the scanning suite. The infusions began exactly 6 min after the start of the 12 min scans and lasted 60 s. The subjective effects of psilocybin were felt almost immediately after injection and sustained for the remainder of the scanning session. This experimental approach thus provided four distinct fMRI recordings (6 min each) corresponding to each of four experimental conditions: pre/post placebo injection and pre/post psilocybin injection. To account for potential confounds related to the infusion event and to focus analyses on the active drug state, the last 5 min of each scan were used for the relevant analyses. In order to have BOLD timeseries of equal length pre- and post-injection, only the first 5 min of scanning (pre-infusion) were considered in the analysis. At the end of each session, subjects were asked to rate the overall intensity of their subjective experience under the drug (or placebo) and to comment on their wakefulness level throughout the scan. As expected, all participants rated the subjective effects of psilocybin (mean intensity = 6.9/10 ± 2.6) as much stronger than placebo (mean intensity = 0.4/10 ± 0.6) and none of the subjects reported falling asleep during either scanning session.

6. Neuroimaging data acquisition & processing

6.1. Anatomical scan acquisition

Neuroimaging data were acquired using a 3T GE HDx MRI system. Anatomical scans were performed before each functional scan and thus prior to administering either the drug or placebo. Structural scans were collected using a 3D fast spoiled gradient echo scans in an axial orientation, with field of view = 256 × 256 × 192 and matrix = 256 × 256 × 192 to yield 1 mm isotropic voxel resolution (repetition time/echo time TR/TE = 7.9/3.0 ms; inversion time = 450 ms; flip angle = 20).

6.2. fMRI acquisition

BOLD-weighted fMRI data were acquired using a gradient echo planar imaging sequence, TR/TE 3000/35 ms, field-of-view = 192 mm, 64 × 64 acquisition matrix, parallel acceleration factor = 2, 90 flip angle. Fifty-three oblique axial slices were acquired in an interleaved fashion, each 3 mm thick with zero slice gap (3 × 3 × 3 mm voxels).

6.3. fMRI processing

fMRI data were processed using MELODIC (Multivariate Exploratory Linear Decomposition into Independent Components) (Beckmann and Smith, 2004), part of FSL (FMRIB's Software Library, www.fmrib.ox.ac.uk/fsl). The default parameters of this imaging pre-processing pipeline were used on all participants: motion correction using MCFLIRT (Jenkinson *et al.*, 2002), non-brain removal using BET (Smith, 2002), spatial smoothing using a Gaussian kernel of FWHM 5 mm, grand-mean intensity normalization of the entire 4D dataset by a single multiplicative factor and linear de-trending over 50 s intervals.

We used the Anatomical Automatic Labeling (AAL) atlas (Tzourio-Mazoyer *et al.*, 2002) to parcellate the MNI brain into $N = 90$ cortical and sub-cortical non-cerebellar brain areas and the BOLD signals were then averaged over all voxels belonging to each brain area using FSL tools. The BOLD signals in each of the 90 brain areas were subsequently band-pass filtered between 0.02 and 0.1 Hz (using a 2nd order Butterworth filter), discarding in this way the high frequency components associated to cardiac and respiratory signals (>0.1 Hz), and focusing on the most meaningful frequency range of resting-state fluctuations (Biswal *et al.*, 1995).

For each subject, this procedure was applied separately to the fMRI data from all four experimental conditions listed above, resulting in four NxT BOLD datasets where $N = 90$ is the number of brain areas and $T = 100$ is the number of TRs.

7. Dynamic BOLD phase-locking analysis

To compute the phase alignment between each pair of AAL regions, first the BOLD phases, $\theta(n,t)$, were estimated using the Hilbert transform for each BOLD regional timecourse (see Fig. 1A) (Glerean *et al.*, 2012; Cabral *et al.*, 2017b). The Hilbert transform expresses a given signal x as $x(t) = A(t)*\cos(\theta(t))$, where A is the time-varying amplitude and θ is the time-varying phase. In Fig. 1A, we represent the BOLD signal phase of one area n over time as $e^{i\theta(t)}$ with $\sin(\theta(t))$ representing the imaginary part of the analytic phase, and $\cos(\theta(t))$ representing its real part (black dotted lines). We show that $\cos(\theta(t))$ captures the oscillatory dynamics of the original BOLD signal (green) - which is mostly preserved after band-pass filtering between 0.02 and 0.1 Hz (blue) - but with constant amplitude (i.e., between -1 and 1). The arrows in red represent the Hilbert phases at each TR, which can be projected into the complex plane (i.e., the plane defined by the real and imaginary axes, represented at $t = 0$).

Fig. 1B shows, at a single time point t, all N = 90 BOLD phases in the cortical space, placed at the center of gravity of each brain area. Here, the arrows are colored according to their direction when projected into the leading eigenvector of phase coherence. On the middle of panel B, the same N = 90 BOLD phases are plotted in the complex plane, i.e., all centered at the same origin.

To obtain a whole-brain pattern of BOLD phase coherence at each single time point t, we compute a dynamic Phase-Locking matrix dPL(n,p,t) which estimates the phase alignment between each pair of brain areas n and p at each time t using Equation (1):

$$\mathrm{dPL}\,(n, p, t) = \cos(\theta(n, t) - \theta(p, t)). \qquad (1)$$

Using the cosine function, two areas n and p with temporarily aligned BOLD signals (i.e., with no phase difference) at a given TR will have a phase-locking value $dPL(n, p, t) = \cos(0°) = 1$. On the other hand, time points when the BOLD signals have180° phase difference (in complex plane) will have $dPL(n, p, t) = \cos(180°) = -1$. The cosine function being even, the $dPL(t)$ matrix is symmetric with values ranging between -1 and 1.

The resulting *dPL* for each subject in each condition is thus a three-dimensional tensor with size *NxNxT*, where $N = 90$ is the number of brain areas and $T = 100$ is the total number of time points.

Fig. 1. Detection of recurrent BOLD phase-locking (PL) patterns. A) The BOLD signal in a given brain area n (green) is first band-pass filtered between 0.02 and 0.1 Hz (blue) and then transformed into an analytic signal (with real and imaginary components) using the Hilbert transform. The phase dynamics of the analytic signal can be represented over time by $e^{i\theta}$ (black line), where the real part is captured by cos(θ) and the imaginary part by sin(θ) (black dotted lines). The red arrows represent the BOLD phases at each TR. **B)** At a single time point, the BOLD phases in all N = 90 brain areas are represented both in the cortical space (arrows centered at the center of gravity of each brain area) and in the complex plane (i.e., the unit circle with real and imaginary axes, where all phases are centered at the same origin). The phase-locking matrix at time t captures the BOLD phase alignment between each pair of brain areas. (Right) The leading eigenvector of the phase-locking matrix at time t, $V_1(t)$, is the vector that best captures the main orientation of all BOLD phases (represented as a black dashed arrow in the unit circle in the left), where each element in $V_1(t)$ corresponds to the projection of the BOLD phase in each area into $V_1(t)$. The elements of $V_1(t)$ are colored according to their relative direction with respect to V_1 (red: positive; blue: negative). **C)** We take the leading eigenvector $V_1(t)$ as a low-dimensional representation of the BOLD phase-locking patterns over time. To identify recurrent phase-locking patterns, we apply a clustering algorithm (k-means), which divides the pool of data points into a predefined number of clusters k. Each cluster is represented by a central vector, which we take to represent a recurrent BOLD phase-locking pattern, or PL state.

7.1. Leading eigenvector of the phase-locking matrix

To characterize the evolution of the dPL matrix over time with reduced dimensionality, we employed a method termed Leading Eigenvector Dynamics Analysis (LEiDA) (Cabral *et al.*, 2017b; Figueroa *et al.*, 2019). The leading eigenvector of the NxN phase-locking matrix at time t, $V_1(t)$, is a Nx1 vector that captures the main *orientation* of BOLD phases over all areas, where each element in $V_1(t)$ represents the projection of the BOLD phase in each brain area into the leading eigenvector (Fig. 1B, right). When all elements of $V_1(t)$ have the same sign, all BOLD phases are pointing in the same direction (half-plane) with respect to the orientation determined by $V_1(t)$, which is indicative of a global mode governing all BOLD signals. If instead the first eigenvector $V_1(t)$ has elements of different signs (i.e., positive and negative), the BOLD signals follow different directions with respect to the leading eigenvector, which naturally divides the brain areas into 2 clusters according to their BOLD phase relationship (see Fig. 1B). Moreover, the magnitude of each element in $V_1(t)$ indicates the 'strength' with which brain areas belong to the communities in which they are placed (see Newman (2006) and the Supplementary Information for further details). Since V and -V span the same one-dimensional subspace, we use a convention ensuring that most of the elements have negative values, because, as we will show, our results revealed that the smallest group of areas whose BOLD phases do not follow the global mode reveal meaningful functional brain networks (i.e., canonical resting-state networks).

This approach substantially reduces the dimensionality of the data, while still explaining most of the variance of BOLD phase coherence (see the Supplementary Fig. S1 where we show that the leading eigenvector consistently represents >50% of the variance in phase coherence at all time points).

8. BOLD phase-locking states

8.1. Detection of recurrent BOLD phase-locking patterns

To identify recurrent PL patterns, we applied a k-means clustering algorithm to divide the set of 1800 eigenvectors (corresponding to all 100 TRs of all 9 subjects both before and after psilocybin injection) into a predefined number of clusters *k* (see Fig. 1C), with higher k revealing more rare and more fine-grained patterns. Since the optimal number of functional networks to consider remains an open question, we ran the k-means clustering algorithm with *k* ranging from 5 to 10 (i.e., dividing the set of eigenvectors into *k* = 5, 6, ..., 10 clusters) to cover the range of functional networks commonly reported in the resting-state fMRI literature (Beckmann *et al.*, 2005; Damoiseaux *et al.*, 2006; Yeo *et al.*, 2011).

For each partition model considered (i.e., k = 5 to k = 10), the clustering returns *k* cluster centroids in the shape of Nx1 vectors V_C, which represent the average vector of each cluster (in Fig. 2A we show the 7 central vectors obtained with k = 7; the centroids obtained for all solutions ranging from k = 5 to k = 10 are shown in Supplementary Fig. S2). We take these central vectors as representing recurrent BOLD phase-locking states, or PL states. As shown in Fig. 2B, each PL state can be represented as a network in cortical space, where the value of $V_C(n)$ is used to scale the color of each brain area and links are plotted between areas with positive sign to highlight the network detaching from the global mode (in Fig. 2 we used $V_C(n) > 0.3$ for visualization purposes only). Also, to facilitate visualization and interpretation of PL states, the cluster centroid vectors V_C can be rendered onto a cortical surface, e.g. using the HCP Workbench (Fig. 2C). Finally, we note that the PL states can also be represented back into matrix format (NxN) by computing the outer product $V_C. V_C^T$ resulting in a matrix of rank 1 (i.e., a matrix that is obtained from a single vector), with positive values between all elements with the same sign in V_C (be they positive or negative), and negative values between elements of different signs (Fig. 2D).

8.2. Probability of occurrence and switching profiles of PL states

The clustering assigns to each TR a single PL state, by selecting the closest centroid V_C at each TR, as illustrated by the color-coded bars in Fig. 3A for one representative subject (the color-coded cluster time courses are shown for all 9 subjects in Supplementary Figs. S3 and S4). Using the state time courses, we calculated the probability of occurrence of each state, which is simply the number of epochs assigned to a given PL state divided by the total number of epochs (TRs) in each scanning session (see Fig. 3A for an illustration with k = 7). For each partition model (i.e., with k = 5 to k = 10) the probabilities of each PL state were calculated for each subject before and after psilocybin injection separately.

Differences in probabilities of occurrence before and after injection were statistically assessed using a permutation-based paired *t*-test. This non-parametric test uses permutations of group labels to estimate the null distribution, which is computed independently for each experimental condition (before versus after psilocybin injection). For each of 1000 permutations, a *t*-test is applied to compare populations and a *p*-value is returned.

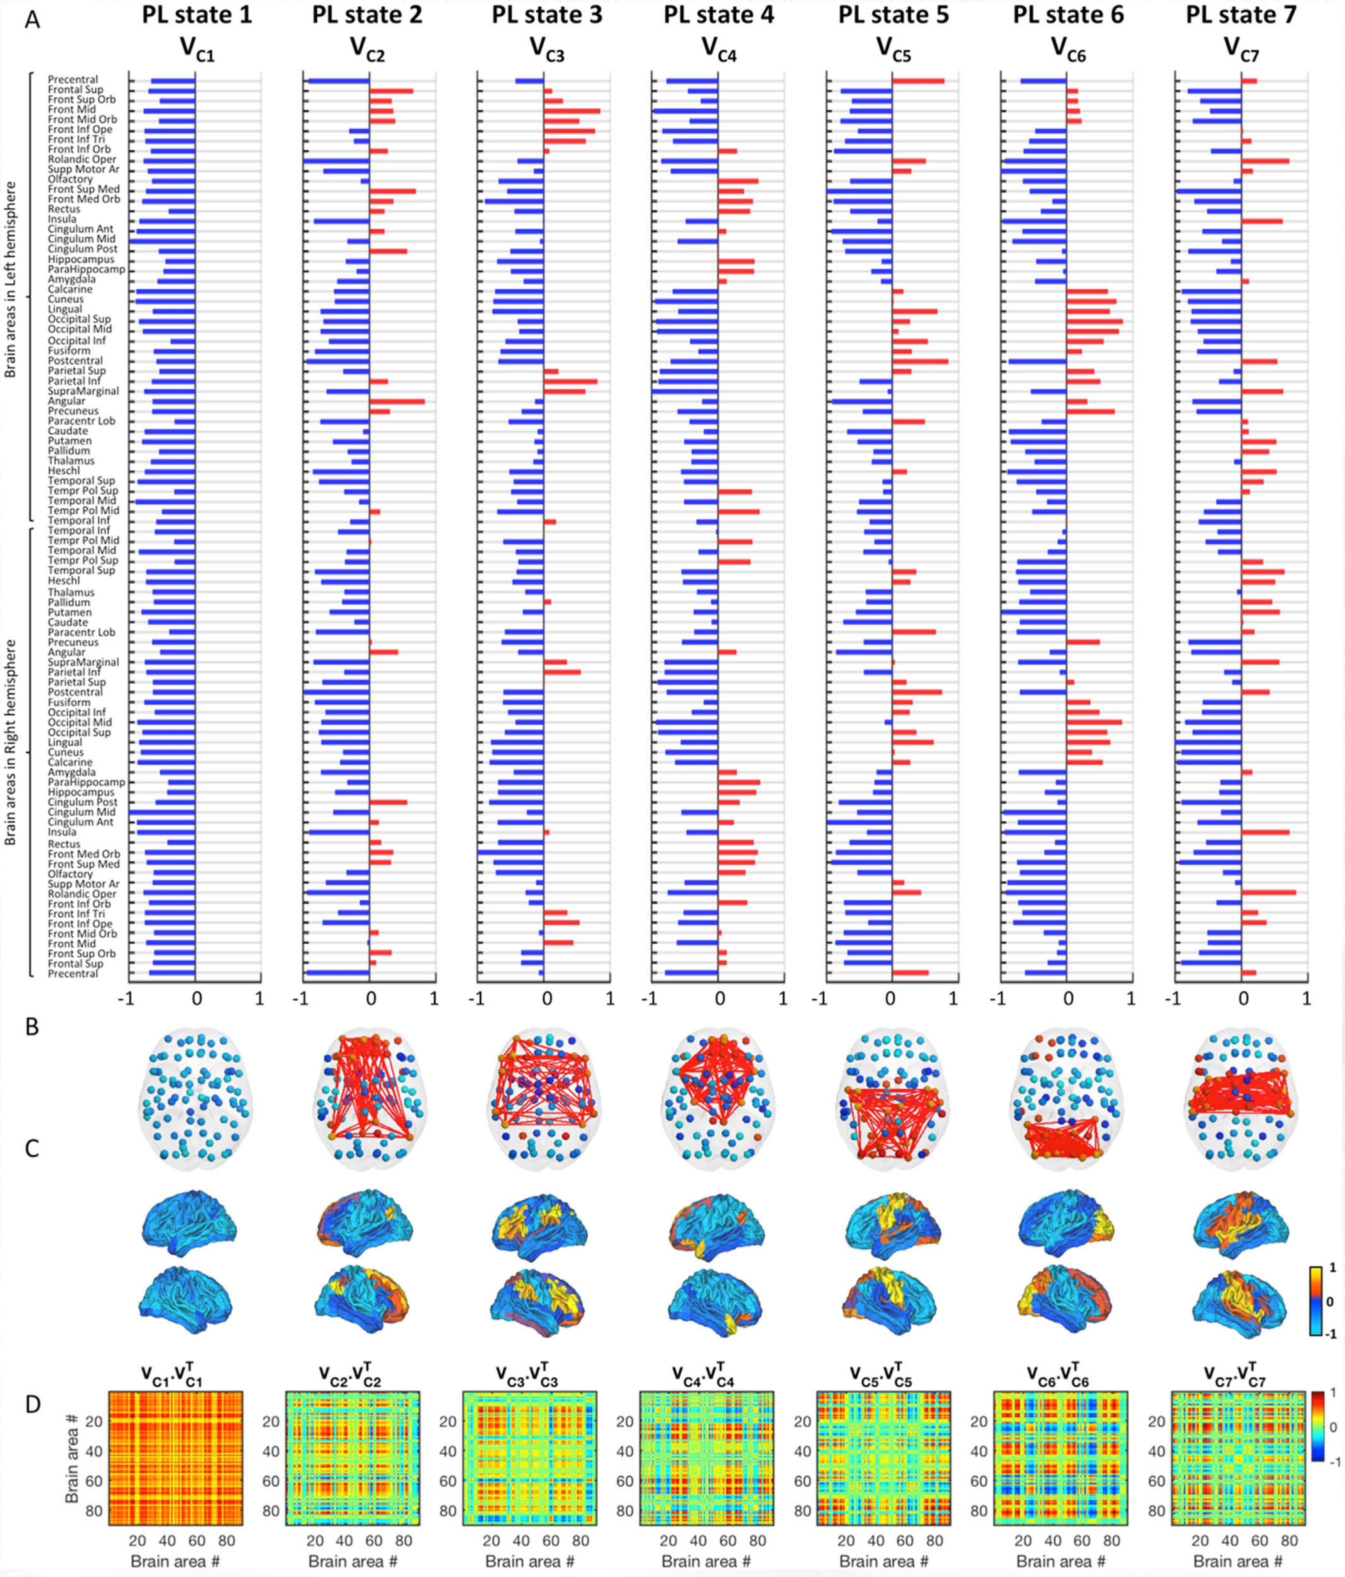

Fig. 2. Repertoire of recurrent BOLD phase-locking patterns (PL states) obtained by clustering the leading eigenvectors of BOLD phase coherence (here with k = 7). Seven recurrent PL states were obtained from unsupervised clustering of the 1800 eigenvectors of BOLD phase coherence over time, sorted (left to right) according to decreasing probability of occurrence before psilocybin injection. Each PL state is represented by the central vector of each cluster V_C as: **A)** a bar plot showing the N elements in V_C, representing the projection of the BOLD phase in each brain area into the leading eigenvector; **B)** a network in cortical space, where the value of $V_C(n)$ is used to scale the color of each brain area and links are plotted between areas with $V_C(n) > 0.3$ to highlight the network detaching from the global mode; **C)** cortical renderings in AAL space of regional contributions to the respective V_C and **D)** a matrix obtained by calculating the outer product of V_C, where positive values are the product of V_C elements with the same sign, be they positive or negative.

8.3. Selection of the optimal number of PL states

In the current study we did not aim to determine the optimal number of PL states governing resting-state activity, but rather to investigate if there are PL state(s) that significantly differ in their probability of occurrence following the administration of psilocybin. As such, we employed a data mining approach to detect meaningful activity patterns (PL states) from the session during which psilocybin was infused, and left the placebo session (recorded more than 7 days apart) as a validation dataset (see section *Validation using the Placebo dataset*).

To search for PL patterns affected by psilocybin, we varied k (number of clusters) between 5 and 10, and for each k examined how the probability of occurrence of each PL state changed after the injection of psilocybin. We subsequently analyzed the robustness of the results over the range of partition models by plotting the p-values with respect to different significance thresholds, i.e., the standard $\alpha_1 = 0.05$ or the Bonferroni corrected significance threshold $\alpha_2 = 0.05/k$ to correct for the number of independent hypotheses compared in each partition model.

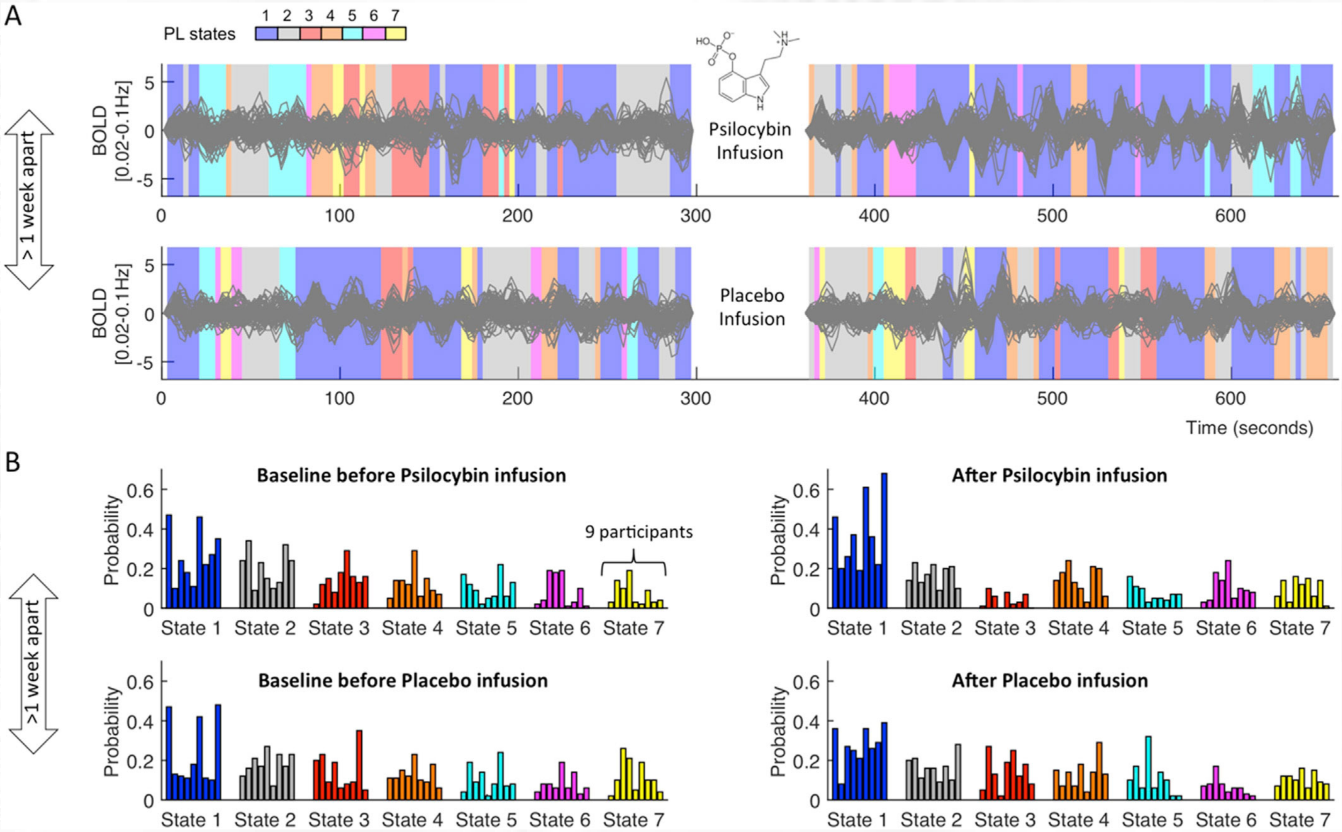

Fig. 3. Assignment of one BOLD Phase-Locking (PL) state to each TR and corresponding probabilities of occurrence for each condition and participant. A) For each of the 9 participants, 2 fMRI sessions were recorded at least one week apart. In the middle of each session, either Psilocybin or a Placebo was intravenously administered inside the scanner. The color-coded bars behind the BOLD signals represent the PL state assigned to each TR (corresponding to the 7 PL states reported in Fig. 2). Results are shown here for subject 9 (the remaining participants are shown in SI Figs. S3 and S4). **B)** The probabilities of occurrence of each PL state were obtained for each of the 4 conditions and for each subject separately, which were used for the subsequent statistical analysis.

For the subsequent validation using the placebo condition, we used exactly the same PL states obtained previously for the psilocybin session for the selected optimal k, and evaluated how these same PL states were explored during the placebo session. As in the previous analysis, we first obtained the 1800 leading eigenvectors V_1 (9 subjects, 2 conditions, 100 TRs each) and ran a *single* iteration of the k-means algorithm with $k = 7$, defining as 'start vectors' the 7 cluster centroids V_C obtained before. This computes the cosine distance between each observation in the placebo dataset and the previously defined 7 cluster centroids, returning a sequence of cluster time courses for the placebo fMRI session. Critically, this approach allows a direct comparison with the psilocybin fMRI sessions recorded several days apart, enabling us to verify whether the probabilities of approaching a given cluster centroid in the placebo sessions were: i) consistent with the pre-psilocybin condition and ii) different from the post-psilocybin condition.

In a follow-up analysis, we compared the number of within-subject occurrences of the most meaningful PL states before and after the psilocybin injection using a paired *t*-test.

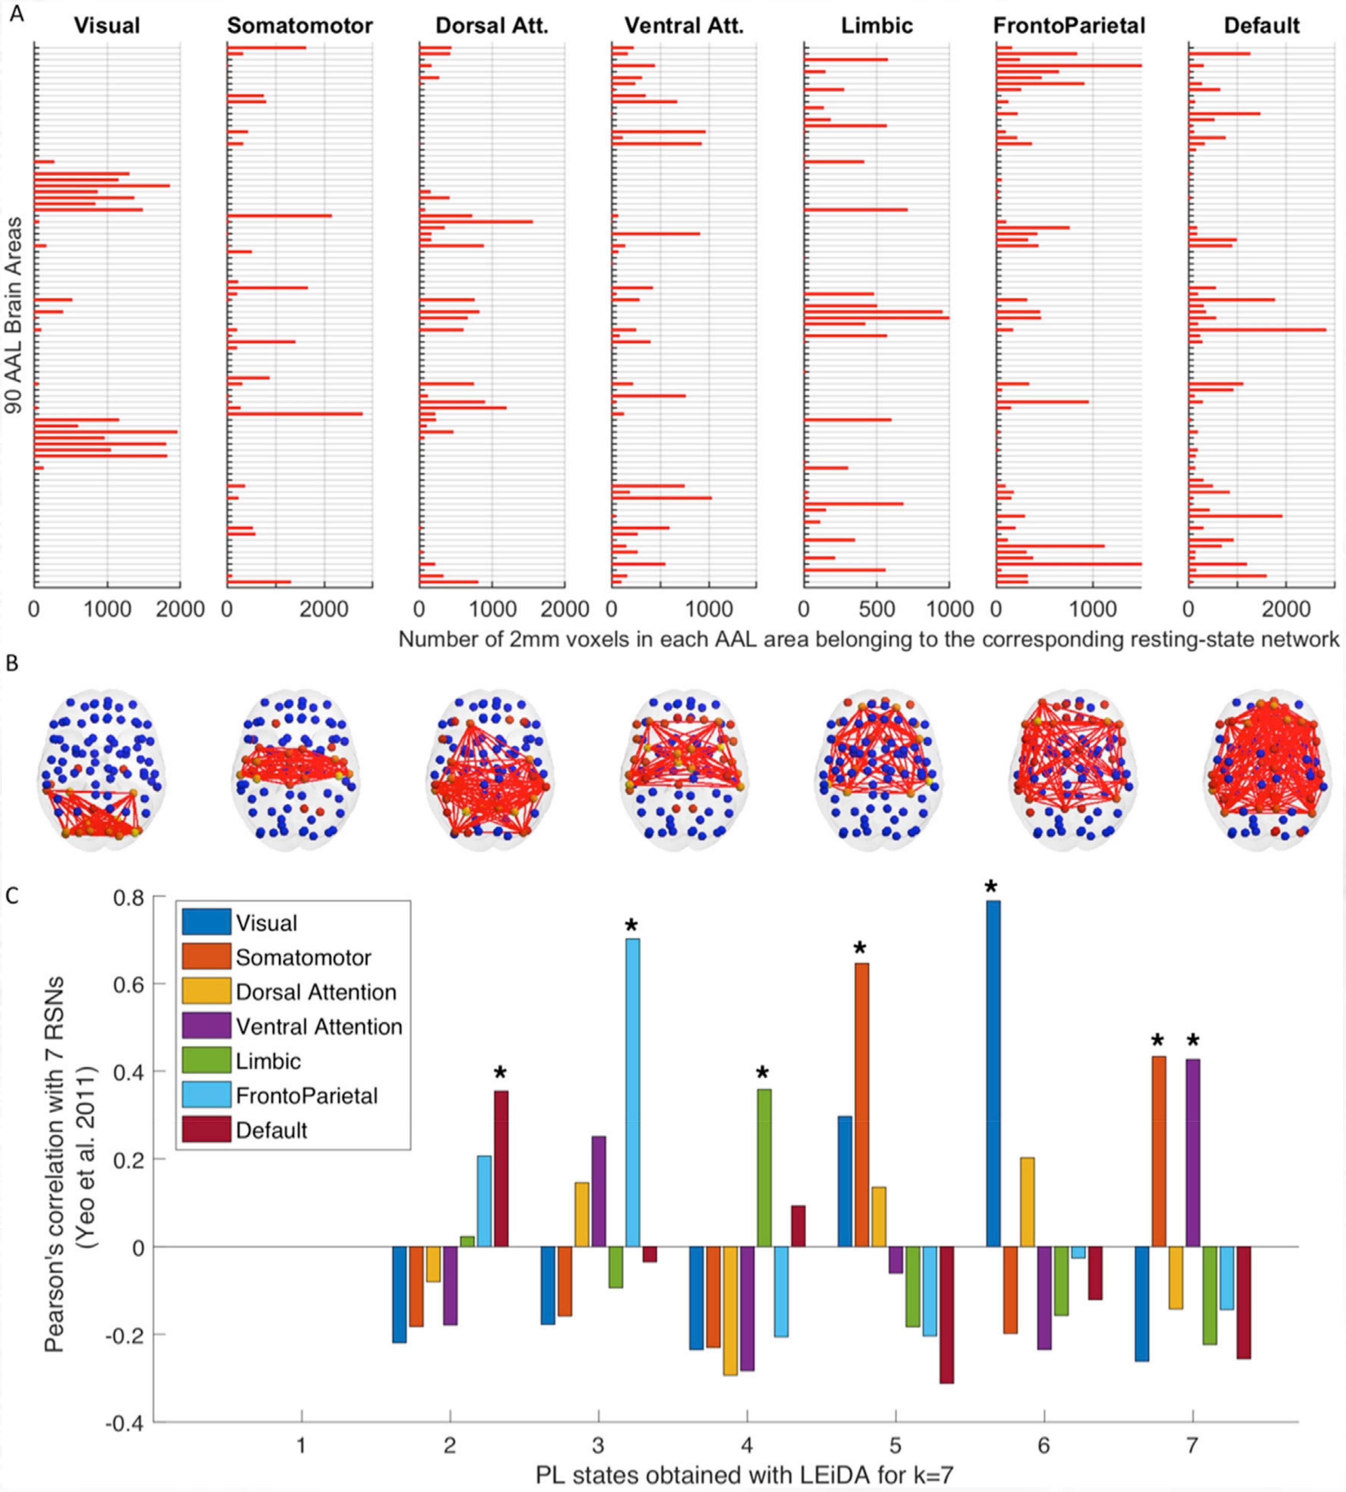

Fig. 4. Overlap of the 6 non-global PL states with seven canonical resting-state networks (RNSs). A) The 7 cortical networks defined in Yeo *et al*. (2011) were transformed into AAL space by counting the number of 2 mm^3 MNI voxels in each AAL brain area that belong to each of the 7 networks, obtaining in this way a vector with N = 90 elements that we can compare with the PL states obtained in this work. **B)** Representation in cortical space of the vectors shown in (A) colouring in red the spheres representing the brain areas contributing to each RSN. Red links were plotted between AAL areas with >400 MNI voxels contributing to each RSN. **C)** We compared the 6 non-global PL states obtained with LEiDA (for k = 7) with the 7 RSNs by computing the Pearson's correlation between the 1 × 90 centroid vectors V_C (shown in Fig. 3) and the vectors shown in (A). Asterisks denote significant correlations with p-value < 0.001.

8.4. Comparison with resting-state networks

We first transformed the 7 RSNs defined in 2 mm^3 MNI space by Yeo *et al*. (2011) into 7 vectors with 90 elements each (shown in Fig. 4), where each element scales the contribution of each AAL brain area to the corresponding RSN. Subsequently, we computed the bivariate correlation with the centroid vectors V_C, setting all negative elements in V_C to zero, keeping only the values of the positive elements (the red links in Fig. 2B).

8.5. Global order and metastability

Using a perspective from dynamical systems theory, we investigated how psilocybin affected the order and stability of BOLD signals. At each instant of time, the degree of order between BOLD phases $\theta(n, t)$, $n = 1,..,90$, can be quantified using the magnitude of the Kuramoto Order Parameter, $OP(t)$, which can range between 0 (when all BOLD signals are out of phase) and 1 (when all BOLD signals are in phase):

$$\mathrm{OP(t)=1N|\sum n=1Nei\theta(n,t)|.}$$

The mean magnitude of the Order Parameter over time informs whether the system is mostly incoherent, partially synchronized or fully synchronized (Acebrón *et al*., 2001; Acebrón *et al*., 2005; Cabral *et al*., 2011; Deco and Kringelbach, 2016). Moreover, the standard deviation of the order parameter, STD(OP), can be used to characterize the degree of *metastability* in the system (Shanahan, 2010; Cabral *et al*., 2014b). In other words if the order parameter is constant over time, it means that the system is in a stable equilibrium, be it synchronized or not. When more than one weakly stable states co-exist and the system systematically switches from one to another, then the variance of the order parameter increases, indicating a dynamical system with metastability. To investigate the effects of psilocybin on the stability of the global order of BOLD phases, we therefore calculated the standard deviation of the order parameter over time within each subject before and after the psilocybin infusion. Between-condition differences on these measures were assessed using a one-sample *t*-test.

9. Data and code availability statement

fMRI data from the 9 participants in the 4 conditions is available on request. Please contact Robin L Carhart-Harris r.carhart-harris@imperial.ac.uk at the Centre for Psychedelic Research, Department of Brain Sciences, Imperial College London.

The Matlab codes developed for the analysis are made available open source at github.com/juanitacabral/LEiDA_Psilocybin, together with the post-processed data.

10. Results

10.1. Repertoire of PL states reveals canonical resting-state networks

The repertoire of PL states obtained when dividing the set of leading eigenvectors into seven clusters is plotted in Fig. 2, where each state is represented by its central vector V_C as: (A) a bar plot showing the projection of the BOLD phase in each brain area into the leading eigenvector, (B) a network in cortical space, where links are plotted between areas with $V_C(n) > 0.3$ to highlight the network detaching from the global mode; (C) a rendering of regional values of V_C onto the cortical surface, and (D) a matrix obtained by calculating the outer product of V_C. While partitions with different *k* were produced, we selected the partition into k = 7 PL states because it returned the PL states that most significantly differed in terms of probability of occurrence after psilocybin injection, as we will explain in section *Results - Consistency of between-condition differences across partition models.*

Results reveal that the most probable BOLD phase-locking state (PL state 1) corresponds to a state where all

BOLD signals are following one main direction (i.e., all projecting toward the same direction into the leading eigenvector), in line with findings from prior studies using LEiDA (Cabral *et al.*, 2017b; Figueroa *et al.*, 2019). While this global modulation occurs for a significant fraction of the time, we detect a number of non-global patterns that transiently and recurrently shape the phase alignment of BOLD signals during the remaining time.

The non-global PL states 2-7 shown in Fig. 3 reveal striking spatial similarities with canonical resting-state networks reported in the literature. We verified this overlap by computing the correlation between the 7 resting-state networks (RSNs) defined in Yeo *et al*. (2011) and each PL state obtained herein (Fig. 4). Corroborating our observations, we found that all non-global PL states show strong and statistically significant spatial overlap with well-documented resting-state networks, namely PL state 6 reveals a strong correlation with the Visual network (Pearson's $r = 0.79$, $p = 2.3*10^{-20}$), PL state 3 correlates with the Frontoparietal network ($r = 0.70$, $p = 1.1*10^{-14}$), PL state 5 correlates with the Somatomotor network ($r = 0.65$, $p = 6.1*10^{-12}$), PL state 4 correlates with the Limbic network ($r = 0.36$, $p = 5.5*10^{-4}$) and PL state 2 correlates with the Default Mode network ($r = 0.35$, $p = 5.5*10^{-4}$). Finally, PL state 7 reveals approximately equal contributions of the Ventral Attention ($r = 0.43$, $p = 2.0*10^{-5}$) and the Somatomotor networks ($r = 0.43$, $p = 2.8*10^{-5}$).

10.2. Consistency of between-condition differences across partition models

The repertoire of PL states obtained depends on the number of clusters k defined in the k-means clustering algorithm, with a higher k generally revealing more fine-grained, less frequent and often less symmetric networks. Here, we chose to cover a range of partition models (i.e., with k varying gradually between $k = 5$ to $k = 10$) and examined the PL configurations that most significantly differentiate brain activity under psilocybin in each partition model relative to the pre-injection baseline.

In Fig. 5, we show, for each partition into k PL states (horizontal axis), the p-values obtained from between-condition comparisons (pre vs post-psilocybin) in terms of probability of occurrence of each of the corresponding k PL states. Since a higher number of comparisons increases the chances of false positives (i.e., of p-values falling below the standard threshold of $\alpha_1 = 0.05$, shown in red in Fig. 5C), we Bonferroni correct the threshold by the number of independent hypotheses tested within each partition model, i.e., $\alpha_2 = 0.05/k$ (green dashed line in Fig. 5C). Note that across partition models, the null hypotheses being tested are not independent from each other (as shown in the correlations reported in Fig. 5D), so correcting for the full number of comparisons would not be adequate here.

We find that, for the entire range of partition models explored (i.e., $5 \leq k \leq 10$), the PL state that most strongly alters its probability of occurrence after the psilocybin infusion is a frontoparietal network (Fig. 5A) passing the corrected threshold α_2 for all k except for $k = 6$ ($p = 0.0095$), which despite falling below α_1, narrowly misses the α_2 cutoff. The most significantly different PL state of each partition model is reported in Fig. 5B in vector format. These PL states were highly correlated across clustering solutions (CC > 0.86 for all pairs of PL states, Fig. 5D), which indicates that they refer to the same underlying functional network, with small differences arising from the number of output states constrained by k. Furthermore, we note that a second network exhibited significant differences between conditions surviving the correction for the number of clusters ($\alpha_2 = 0.05/k$) for the clustering solutions: $k = 5$ ($p = 0.0078$) and $k = 7$ ($p = 0.0068$) (Fig. 5C, second smallest p-value for each k). This network corresponds to the globally coherent PL state 1, which also showed a high level of consistency across the range of clustering solutions, with some brain areas being more strongly aligned to the global mode of BOLD phase coherence than others (see Supplementary Fig. S2).

Fig. 5. Detection of the PL states that most significantly change their probabilities of occurrence after psilocybin infusion across partition models. A) The PL state differing the most between conditions is a functional network consisting of lateral frontoparietal areas, shown here for k = 7 (PL state 3 from Fig. 2). B) Bar plots showing, for each partition into k = 5 up to k = 10 PL states, the cluster centroid of the PL state that most significantly changed in probability of occurrence between conditions (p-values reported in the title are colored according to significance level). **C)** For each partition model, we plot the p-values associated to the comparison between all PL state probabilities before and after psilocybin injection. We find that, although most PL states do not show significant differences between groups (black dots falling above the α_1 = 0.05 threshold), some PL states show significant differences in probability of occurrence between groups, falling below (or very near for k = 6) the corrected threshold by the number of clusters (α_2 = 0.05/k, green dashed line). **D)** The PL states representing the Frontoparietal network in different partition models (shown in B) are highly correlated with one another.

10.3. Network-specific neuromodulation

The probabilities of occurrence of each PL state in each of the 4 experimental conditions for the optimal solution with k = 7 are shown in the bar plots of Fig. 6B. As predicted from the previous analysis, we find that for k = 7, psilocybin significantly alters the occurrence of two of the seven BOLD phase-locking modes. The probability of occurrence of PL state 3 (red) significantly decreased from 14.3 ± 2.4% pre-injection (third most visited state) to 4.1 ± 1.2% following the psilocybin administration (p = 0.00034 uncorrected, p' = 0.0021 after correction). Conversely, a significant increase in the probability of occurrence of PL state 1 (dark blue) was also observed, shifting from 26.7 ± 4.5% pre-psilocybin injection to 37.2 ± 6.0% post-psilocybin injection (p = 0.0068 uncorrected, p' = 0.047 after correction). In contrast, the probability of occurrence of all other PL states remained statistically similar before and after the psilocybin infusion (all p-values > 0.05).

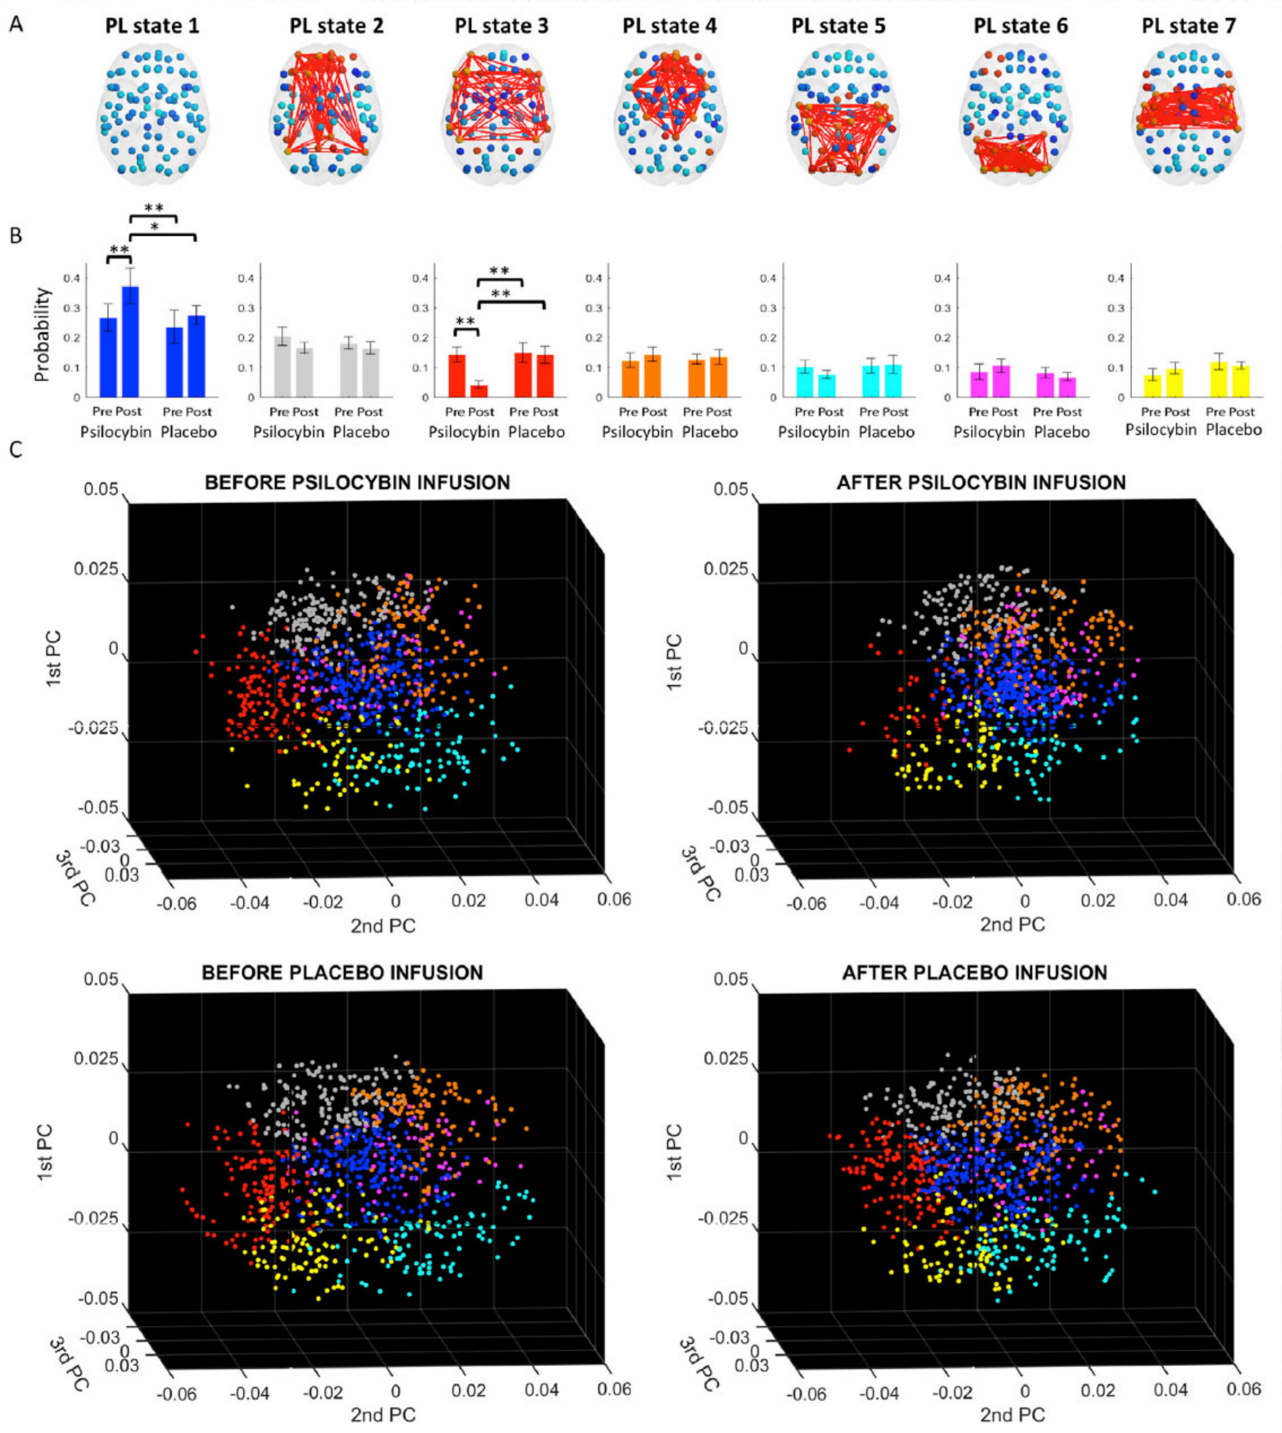

Fig. 6. Psilocybin modulates the exploration of BOLD Phase-Locking configurations. A) Repertoire of PL states detected with LEiDA for k = 7 from the session when psilocybin was infused (same as shown in Fig. 2). **B)** Probability of occurrence (mean ± standard error of the mean across subjects) of each PL state in each of the four experimental conditions (pre/post psilocybin and pre/post placebo injection). We find that after the infusion of psilocybin, PL state 3 (red) significantly decreases in probability of occurrence from an average of 14.3-4.1% ($p = 0.00034$), whereas PL state 1 (blue) significantly increases after psilocybin injection ($p = 0.0068$). All other PL states did not change in fractional occupancy with psilocybin. Importantly, when the BOLD phase leading eigenvectors from the placebo session (900 before and 900 after infusion) were matched to the 7 PL cluster centroids obtained from the psilocybin session, we found that *all* the probabilities of occurrence were consistent with the resting state *before* psilocybin injection (despite being more than a week apart), and exhibited the same significant differences with respect to the psilocybin condition. Asterisks denote the presence of statistically significant differences (* < 0.05; ** < 0.05/k correcting for the number of independent hypotheses tested). **C)** Representation of all PL configurations in each experimental condition on a low-dimensional manifold highlighting the reduced number of occurrences of the Frontoparietal network (red dots) after psilocybin injection. In each scatter plot, each dot represents one PL configuration, captured by $V_1(t)$. Each panel corresponds to a different session (before/after psilocybin/placebo). Dots are colored according to the closest cluster centroid vector, V_C, using the same color code as in B. It can clearly be observed that the number of red dots is substantially reduced after the psilocybin injection. This representation serves to illustrate how the reduced occurrence of the Frontoparietal network under psilocybin can be interpreted in terms of fewer excursions into a specific region of a low-dimensional manifold of network configurations.

10.4. Validation using the placebo dataset

The 7 PL states shown in Fig. 2 were defined solely from half of the fMRI scans in the dataset, i.e., the scans from the 9 participants recorded during the day in which psilocybin was infused (including the pre-injection baseline), consisting of 9 2 100 TRs. Using a data mining approach, we searched for the partition model that returned the most significant differences between pre- and post-injection conditions.

To further validate our findings, we verified whether these same 7 PL states were expressed in the fMRI session during which placebo was infused - recorded more than a week apart -, and if they occurred with similar probabilities as during the baseline condition before psilocybin was injected. To do so, we took exactly the same cluster centroids (shown in Fig. 2A) and evaluated their probabilities of occurrence both before and after the placebo infusion.

Validating our results, we found that the probabilities of occurrence of all 7 PL states both before and after placebo injection did not differ from the baseline condition before psilocybin was infused (all p-values > 0.05). Notably, this indicates that the dynamical exploration of PL states assessed with LEiDA remained stable across subjects under baseline conditions over a period of more than a week (Fig. 6B). Corroborating our previous findings, the fractional occupancy of PL state 3 remained within normal levels both before (15.0 ± 3.3%) and after (14.3 ± 2.9%) placebo injection (p = 0.49 uncorrected), and was in each case significantly higher than the probability of occurrence found during the psychedelic state (4.1 ± 1.2%, p = 0.00057 and p = 0.00014, respectively, both falling below the corrected threshold $\alpha_2 = 0.05/k = 0.007$). Moreover, the probability of occurrence of PL state 1, remained unchanged following the placebo injection (23.6 ± 5.6% versus 27.4 ± 3.1%, p = 0.38), being substantially lower than the probability of occurrence of PL state 1 under psilocybin (37.2 ± 6.0%, p = 0.00051 before, p = 0.012 after placebo injection), with the pre-placebo comparison surviving correction for multiple comparisons with α_2.

10.5. Dynamical exploration in a low-dimensional manifold

The non-stationary dynamics of the PL leading eigenvectors over time can be interpreted as the constant exploration of a cloud of PL configurations in a multi-dimensional space (with N = 90 dimensions in the selected parcellation). In order to visualize this cloud of observations in a low-dimensional manifold (Fig. 6C), we applied a Principal Components Analysis (PCA) to all leading eigenvectors across conditions and subjects (90 × 3600) and used the first 3 Principal Components (3 × 3600) to project each observation in a low-dimensional manifold. In this way, each 90 dimensional leading eigenvector V_1 obtained at each TR can be plotted as a dot in a 3-dimensional (3-D) space defined by the first 3 principal components and colored according to its closest centroid vector, V_C, using the same color scheme from Fig. 6B. By construction, the k-means clustering algorithm produces compact clusters (i.e., non-overlapping and well separated in the 90 dimensional space where the leading eigenvectors are defined). As can be seen in Fig. 6C, retaining the first 3 principal components is sufficient to conserve well-defined clusters (see also Supplementary Fig. S3 to view the 3-D manifolds from a different angle).

This representation serves to illustrate how the occurrence of the different functional networks can be interpreted mechanistically in terms of excursions into distinct regions of a low-dimensional manifold of network configurations. The visual rendition of the data from all subjects in the 4 different experimental conditions shown in Fig. 6C highlights the reduced number of excursions into the region of the manifold associated to the frontoparietal PL state under psilocybin (number of red dots in the upper right-hand plot), compared to the 3 non-psychedelic conditions (before psilocybin and before/after placebo injection). Although less evident, it can also be seen that the blue cluster, corresponding to the globally coherent PL state 1, becomes denser (more dots) after the psilocybin injection. The statistical analysis shown in Fig. 5C serves to define the partition model that optimally delineates the region of the cloud affected after psilocybin injection.

10.6. Trajectories between BOLD phase-locking states

In order to explore the trajectories between the different PL states, we report in Fig. 7 the switching matrices containing the mean probabilities of, being in a given PL state (rows), transitioning to any of the other PL states (columns) both before (left) and after the psilocybin injection (right). Switching probabilities were calculated for each subject and each condition and then statistically compared using a permutation-based paired *t*-test (5000 permutations). To facilitate the interpretation of the differences found in PL state switching profiles, we provide an illustration of the transitions that were most significantly affected by psilocybin (solid red: increased; dashed blue: decreased). We find that the probability of transitioning from any given PL state to the frontoparietal PL state 3 is consistently reduced under psilocybin effects. Conversely, all PL states except one were more likely to transition toward the PL state of global coherence following the psilocybin injection. The p-values for each state-to-state transition in the switching matrix are provided in Supplementary Table ST1.

10.7. Subjective intensity of the psychedelic experience correlates with network occupancy

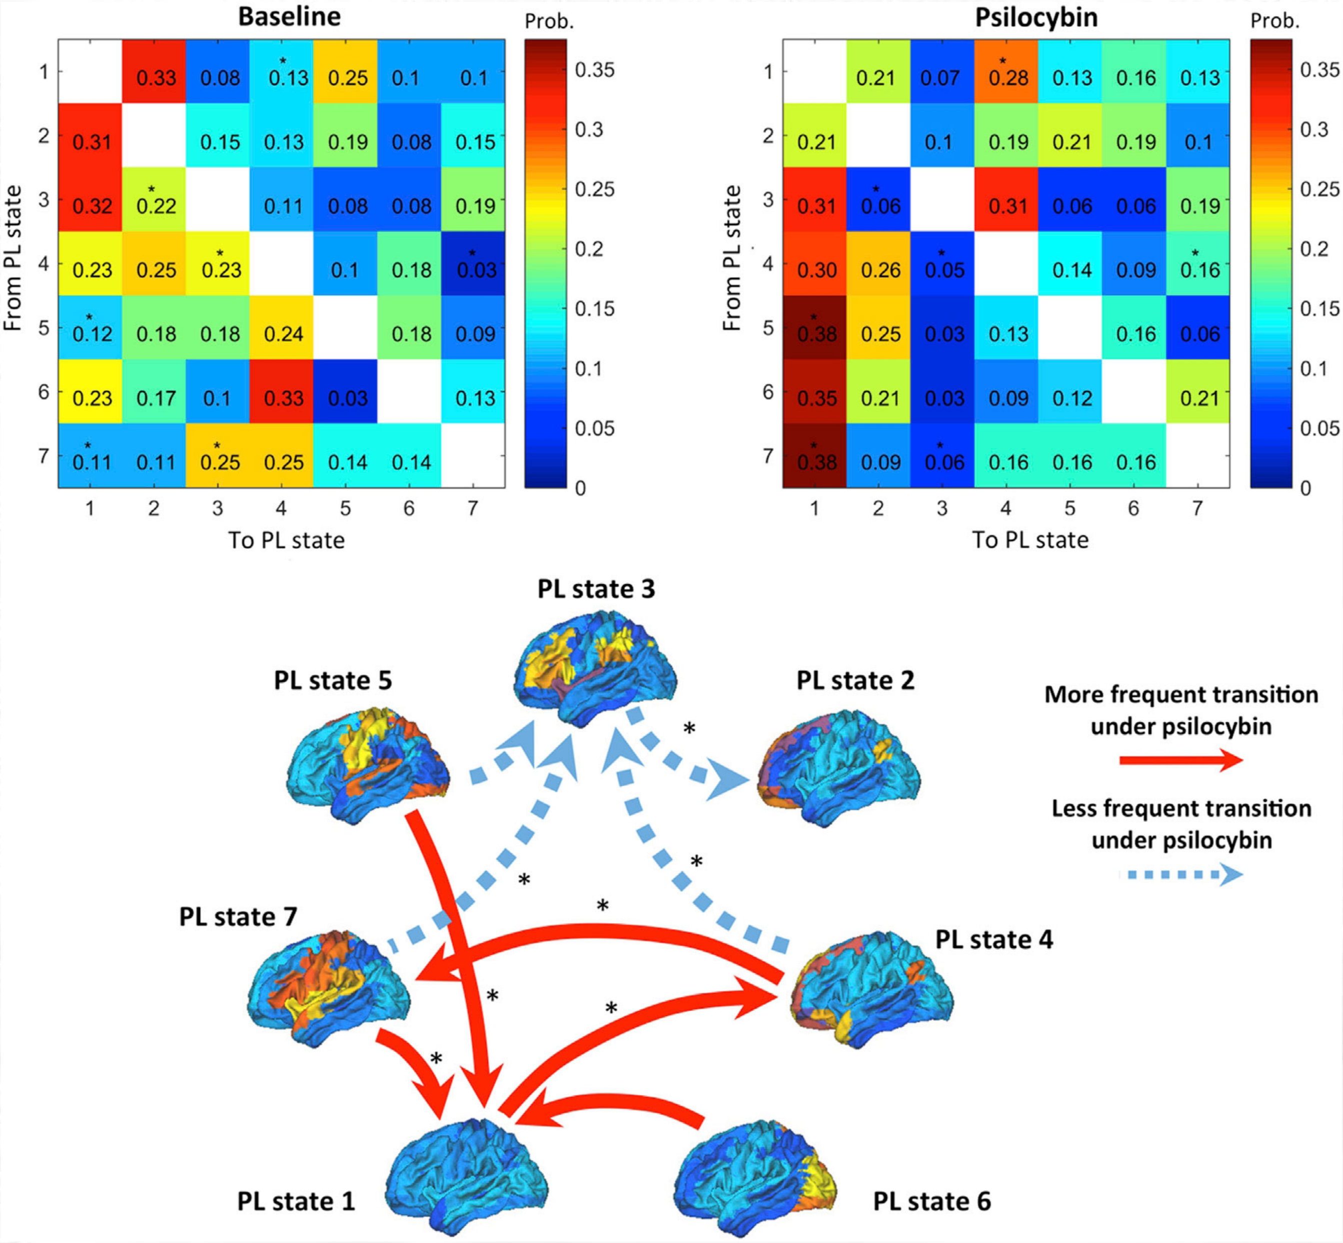
After each scanning session participants were asked to rate the subjective intensity of the psychedelic (or placebo) experience on a scale of 1-10. We correlated those subjective intensity ratings with the probability of occurrence of each of the 7 PL states (Fig. 8). We found that the occurrence of frontoparietal network (PL state 3) was negatively correlated with the subjective rating of the psychedelic experience (Pearson's $r = -0.56$; $p = 0.0083$, one-tailed). Conversely, a near-significant positive correlation was found between the fractional occupancy of the globally coherent PL state 1 and the subjective intensity of the psychedelic experience ($r = 0.36$, $p = 0.07$, one-tailed). Other PL states whose fractional occupancy was not changed by psilocybin did not correlate with this behavioral measure.

10.8. Psilocybin modulates the global order of BOLD phases

We also investigated how psilocybin affected the global order of BOLD phases using the Kuramoto Order Parameter (OP) and, although the mean synchrony degree did not reveal significant differences between conditions ($p > 0.05$), we found that the degree of whole-brain metastability (i.e., how much the synchrony degree fluctuates over time) significantly increased following the psilocybin injection compared to baseline (standard deviation, $STD(OP) = 0.18 \pm 0.01$ vs $STD(OP) = 0.16 \pm 0.015$, $t(8) = 2.41$, $p = 0.04$ using a paired sample *t*-test). In Supplementary Fig. S4, we report the OP over time before and after the psilocybin injection in all subjects.

In addition, we investigated how the OP relates with the different PL states. As expected, we found that the probability of occurrence of the PL state of global coherence (state 1) at the single subject level during a given scan is strongly correlated with the mean of the global OP ($cc = 0.825$, $p = 2.9*10^{-5}$) (Supplementary Fig. S4), indicating that this PL state is associated with an increase in global order, whereas all other PL states are consistently found for epochs of lower OP. In Supplementary Fig. S4, we report the global OP obtained while each of the 7 PL states was active, according to the color-code used in Fig. 6B. This allows a visual representation of all PL state assignments in all subjects at the single TR resolution, showing that PL state 1 is the most frequently visited state - both before and after the psilocybin injection - and also occurs in epochs of high OP, indicating a high level of phase coherence across the network nodes.

Finally, we ran a paired-sample *t*-test to confirm that, at the individual subject level, the mean number of occurrences of PL state 3 (overlapping with the Frontoparietal network) was significantly decreased following the psilocybin injection relative to the pre-injection baseline from 14.3 ± 2.5% to 4.1 ± 1.2% ($t(8) = 3.88$, $p = 0.005$). Conversely, a paired-sample *t*-test showed a significant *increase* in the mean number of occurrences of PL state 1 (globally coherent state) following the psilocybin injection relative to the pre-injection baseline from 26.% ± 4.5% to 37.2 ± 6.0% ($t(8) = 2.75$, $p = 0.01$). These statistical results reinforce the validity of the findings reported in Fig. 6B.



Baseline

From PL state \ To PL state	1	2	3	4	5	6	7

Fig. 8. Subjective intensity rating of the psychedelic experience is related to dynamic exploration of PL states. After the infusion of either Psilocybin (red) or Placebo (blue), participants were asked to rate the subjective intensity of their experience which in each case was far stronger in the psilocybin condition (mean intensity = 6.9 ± 2.6) than placebo (mean intensity = 0.4 ±
0.6) on a scale from 0 to 10. We further investigated the relationship between the subjective ratings and the probability of occurrence of each of the 7 PL states. We found that the occurrence of the frontoparietal network (PL state 3) was negatively correlated with the ratings on psychedelic experience (correlation coefficient cc = -0.56; p = 0.0083, one-tailed), with higher intensity ratings being associated with a lower probability of occurrence of PL state 3 (black lines link the same participant in the placebo (blue) and psilocybin (red) conditions). Conversely, a near-significant positive correlation was found between the fractional occupancy of the globally coherent PL state 1 and the subjective intensity of the psychedelic experience (cc = 0.36, p = 0.073, one-tailed).

10.9. Effect of motion on PL state probabilities

We performed follow-up analyses to confirm that the observed effects of psilocybin on the fractional occupancy of PL state 1 and PL state 3 were not due to differences in participant motion during the scan. For the nine subjects included in the study, we assessed motion by calculating the mean framewise displacement (FD) for each subject. This variable measures movement of any given frame relative to the previous frame. We then conducted two separate analyses to examine the potential effects of motion. First, a paired *t*-test showed that the mean FD was not significantly different between the post-placebo and post-psilocybin injection conditions: t(8) = 1.28, p = 0.24. Furthermore, the fractional occupancy of PL state 3 post-psilocybin did not correlate with the mean FD (correlation coefficient, CC = -0.14, p = 0.72) and neither did the fractional occupancy of PL state 1 post-psilocybin (CC = 0.04, p = 0.91).

11. Discussion

The present study is one of the first to investigate how the exploration of the brain's repertoire of functional networks is rapidly modulated by a psychoactive molecule, here the serotonergic psychedelic psilocybin. Specifically, we found that the dynamical exploration of a fixed repertoire of discrete functional networks at rest, defined as recurrent BOLD phase-locking patterns over time (PL states), is significantly altered after a psilocybin infusion. The strongly reduced expression of a BOLD PL state overlapping with the previously described frontoparietal control system (Vincent *et al.*, 2008; Yeo *et al.*, 2011) suggests that this particular functional subsystem is related to the psychoactive effects of psilocybin. Moreover, we found that the decreased expression of the Frontoparietal network under the influence of the drug only increased the stability of a state of global coherence (PL state 1) and did not change the expression of the remaining PL patterns. These new findings represent one of the first attempts at bridging the gap between molecular pharmacodynamics and the brain's network dynamics.

The highly significant disruption of a BOLD PL pattern closely overlapping with the Frontoparietal control system is consistent with prior human neuroimaging studies of psilocybin's effects. Indeed, a previous analysis of the same dataset revealed that psilocybin modified the BOLD spectral content in a distributed Frontoparietal network. Specifically, the Frontoparietal system of interest showed significantly decreased power at low frequencies (and decreased power spectrum scaling exponent) under psilocybin (Tagliazucchi *et al.*, 2014). Similarly, an MEG study reported decreased oscillatory power under psilocybin in a bilateral Frontoparietal network derived from beta-band activity (Muthukumaraswamy *et al.*, 2013). Findings from these prior studies indicate a rapid desynchronization of the Frontoparietal control system under psilocybin and are thus consistent with the present results. Furthermore, the disengagement of the Frontoparietal system can be interpreted in light of the cognitive and behavioral effects of psilocybin reported by the study participants. Evidence suggests the Frontoparietal system plays a key role in cognitive control by focusing attention on goal-relevant information through top-down mechanisms (Cole and Schneider, 2007; Dosenbach *et al.*, 2008; Xin and Lei, 2015). Such goal-directed focus does indeed appear to be impaired under moderate-high doses of psilocybin (Bayne and Carter, 2018) - which would be a reasonable way of describing the present dosage. Declines in frontoparietal FC have been associated with difficulty suppressing goal-irrelevant information, and greater distractibility (Smallwood *et al.*, 2012). These observations are broadly consistent with the reports of increased freely wandering thoughts and hyper-associative cognition provided by participants in the present cohort (Carhart-Harris *et al.*, 2012; Turton *et al.*, 2014).

It is interesting to consider how the known pharmacodynamics properties of psilocybin could mechanistically explain its destabilizing effect on the Frontoparietal PL state dynamics described above. The psychoactive effects of psilocybin are primarily due to its agonist activity at the serotonin 2A (5-HT_{2A}) receptor (Vollenweider *et al.*, 1998; Kometer *et al.*, 2013). The distribution and density of 5-HT_{2A} receptors in the human brain (and other 5-HT receptor subtypes) were recently estimated in a high-resolution atlas using molecular and structural neuroimaging data in a large cohort of healthy individuals in combination with postmortem human brain autoradiography (Beliveau *et al.*, 2017); 5-HT_{2A} receptors are widely distributed across the brain but most densely expressed in the cortex. Interestingly, the 5-HT_{2A} receptor density map obtained by Beliveau and colleagues shows a strong qualitative overlap between 5-HT_{2A} receptor expression on the lateral surface of the brain, and the regions implicated in the Frontoparietal PL state detected in the present study. Moreover, an fMRI study of the synthetic 5-HT_{2A} receptor agonist and classical psychedelic lysergic acid diethylamide (LSD) has reported significantly increased functional connectivity density (FCD, quantified as the average functional connectivity to the rest of the brain) of a similar Frontoparietal network which, in turn, strongly overlapped with 5-HT_{2A} receptor concentrations (Tagliazucchi *et al.*, 2016). The increase in FCD of the Frontoparietal network can be interpreted as reduced within-network integrity and is thus consistent with the present findings, where the PL state 3 (high within-network coherence and low coherence with the rest of the brain, equivalent to lower FCD) is replaced by the globally coherent PL state 1 (equivalent to higher FCD).

At the cellular level, studies have shown that 5-HT_{2A} receptors are highly expressed in layer 5 pyramidal neurons (Andrade and Weber, 2010). Stimulation of 5-HT_{2A} receptors induces a slow depolarization of pyramidal cells via G-protein coupled signaling pathways as well as the inhibition of the calcium-activated after-hyperpolarization (Andrade, 2011); together these changes make these neurons more likely to fire. Our results are therefore consistent with a scenario in which psilocybin increases the excitability of layer 5 pyramidal neurons broadly in the brain, wherever they are expressed. However, if the expression of 5-HT$_{2A}$ receptors is especially high in lateral frontoparietal areas, then the dysregulated excitation that follows their stimulation (Carhart-Harris, 2019) may, in turn, destabilize this particular system, weakening its stability within the brain's broader repertoire. Supporting this idea, a recent modeling study showed that while the brain's structural connectome plays an important role in constraining and predicting brain dynamics, an additional layer of explanatory power is offered by considering energetic constraints on those dynamics (Gu *et al.*, 2018). Because maintaining functional connections is energetically costly, the brain normally favors efficient neural codes and wiring patterns (Attwell and Laughlin, 2001; Bullmore and Sporns, 2012; Lord *et al.*, 2013). In this framework, the metabolic costs of establishing and maintaining functional connections between anatomically distributed neurons in this Frontoparietal network may become too high following the psilocybin infusion, and brain activity might spend less time in this particular state as a result.

Consistent with this explanation, our analysis revealed increased stability of a functionally non-specific, globally coherent state (PL state 1) following the psilocybin injection. Previous work has indeed shown that the serotonergic psychedelics psilocybin and LSD induce an alternative type of functional integration, characterized by greater global integration (Petri *et al.*, 2014; Roseman *et al.*, 2014; Tagliazucchi *et al.*, 2016) as well as increases in the metastability of brain states (Carhart-Harris *et al.*, 2014). The results presented here not only align with these prior findings but also shed further light on their functional significance. Here we found that a globally coherent state, i.e., PL state 1, increased its predominance under psilocybin, not only statistically over time, but also dynamically, as revealed by the state-to-state switching matrix, where it became the 'state of choice' for inter-state transitions. In other words, under psilocybin the brain spent more time in a globally coherent, highly integrated state. This state therefore served as the dominant attractor, absorbing the majority of inter-state transitions. Residence in this particular, functionally non-specific state is consistent with a flattened attractor landscape where the dominant attractor reflects the relative absence of functionally specific attractors (Carhart-Harris and Friston, 2019). As was implied by previous analyses, this change in global brain dynamics may enable atypical patterns of interregional communication to occur in the psychedelic state (Petri *et al.*, 2014) alongside the breakdown of within-network integrity in favor of globally integrated brain dynamics (Muthukumaraswamy *et al.*, 2013; Carhart-Harris *et al.*, 2014; Petri *et al.*, 2014; Roseman *et al.*, 2014; Tagliazucchi *et al.*, 2016).

In addition to changing the relative stability of PL states and the directionality of state transitions, we found that psilocybin increased the global metastability of brain dynamics. This result is consistent with prior fMRI investigations of the same psilocybin dataset in which a greater diversity of functional connectivity motifs was observed after psilocybin infusion within a small network consisting of the bilateral hippocampal and anterior cingulate brain regions, thus reflecting increased variability in the collective repertoire of metastable states (Tagliazucchi *et al.*, 2014). This prior analysis had purposely limited the number of regions included in order to perform an exhaustive counting of all possible functional connectivity states. Another study had found increased metastability in several canonical resting-state networks as determined by the variance in the networks' intrinsic synchrony over time (relationship between the mean and variance of the signal over time) (Carhart-Harris *et al.*, 2014). Here we used a complementary analytical approach to demonstrate that increased metastability of BOLD phase coherence under psilocybin is generalizable at the whole-brain scale by calculating the standard deviation of the order parameter of the system over time.

The advantage of using a within-subject design (instead of a between-subject design) is that it improves the statistical power of the results. Indeed, despite the fact that there were only 9 subjects included in this fMRI dataset, our findings were strongly validated by the replication of results in the non-drug conditions across the two scanning days (i.e., no significant changes in the occupancy of network states in the placebo scanning session vs pre-psilocybin infusion), as well as the strong statistical effects observed in specific PL states after psilocybin injection (with $p < 0.0005$, surviving correction for the number of independent hypotheses tested). Importantly, since LEiDA compares the statistics between a discrete number of whole-brain PL patterns rather than individual functional links, the number of independent hypotheses tested is reduced from N(N-1)/2 (number of unique links in an NxN symmetric matrix) to the number of states K, which overcomes several of the statistical limitations associated with multiple comparisons in whole-brain dynamic connectivity analysis. Furthermore, given the instantaneous nature of LEiDA, we detected significant between-condition differences despite the fact that each scanning condition consisted only of 100 fMRI volumes, which would likely not have been sufficient for conventional sliding-window analysis (Hindriks *et al.*, 2015). Moreover, we have demonstrated that the changes in the fractional occupancy of specific PL states after the psilocybin infusion was unrelated to participant motion during the scan.

The significant overlap between the BOLD phase-locking patterns detected automatically with LEiDA (from just 1800 fMRI volumes on 9 subjects) and the canonical resting-state networks obtained from ICA analysis on >1000 subjects (Yeo *et al.*, 2011) suggests that the relative phase of the BOLD signals is sensitive to the same underlying patterns captured using ICA procedures, with the advantage that the networks can have spatial overlap and occur transiently at different frames in time. Although our approach did not reveal all the 7 RSNs reported in Yeo *et al.* (2011) - for instance, none of our PL states revealed the Dorsal Attention Network - this difference could be due to our limited sample size and the rather coarse parcellation scheme selected (AAL). Extending this methodological approach to parcellation schemes with a higher number of more homogenous areas (Craddock *et al.*, 2013; Shen *et al.*, 2013; Glasser *et al.*, 2016) is likely to reveal more fine-grained PL states and deserves further exploration. Considering larger sample sizes and higher spatial resolution has the caveat of increasing the computational cost, but as long as the clustering algorithm adequately converges, it is likely to provide additional insights on the mechanisms underlying the formation of these BOLD phase-locking patterns and their relation to well-established RSNs. Importantly, using the cosine function, we focus on phase-locked oscillatory states and do not consider any directed causal influence between BOLD signals, which is fundamentally different to approaches considering asymmetric connectivity measures (Gilson *et al.*, 2016). Regarding the temporal dynamics, we note that the LEiDA approach allows for the analysis of additional temporal properties of BOLD phase-locking patterns, including the dwell time of each state, as in Cabral *et al.* (2017b) and more recently in Figueroa *et al.* (2019). However, the temporal resolution used in the current dataset (TR = 3 s) was too slow to capture more rapid dynamics, which are suggested by MEG studies to operate at time scales of approximately 200 ms (Baker *et al.*, 2014; Vidaurre *et al.*, 2016). As such, we limited our study to the probabilities of occurrence and to the transition profiles occurring over these longer time scales.

The therapeutic potential of psilocybin in psychiatry has recently generated much interest. Indications of efficacy have been reported for conditions including treatment-resistant depression, anxiety related to end-of-life care and addictive disorders (Griffiths *et al.*, 2006; Grob *et al.*, 2011; Johnson *et al.*, 2014; Carhart-Harris *et al.*, 2016). The neural mechanisms underlying these clinical benefits, however, remain unclear. The present results provide some of the first evidence that a psychoactive compound modulates the brain's dynamical repertoire by selectively destabilizing a brain functional network (i.e., frontoparietal control system) and promoting transitions towards a globally coherent PL state. We believe this represents an exciting first step towards bridging molecular pharmacodynamics and dynamical measures of brain function in macro-scale networks, not only for serotonergic psychedelics but potentially across other classes of drugs and neuromodulators. This could have exciting implications for the design of novel therapeutics for neuropsychiatric disorders informed by patho-connectomics, which may be generally understood in terms of targeting the specific PL states affected by a particular disorder with neuromodulatory approaches. Moreover, despite the small sample size and the use of a coarse behavioral measure, we were nevertheless able to show strong associations between the fractional occupancy of certain PL states and the subjective intensity of the psychedelic experience. This interesting proof of concept study represents, to our knowledge, one of the first attempts at linking molecular pharmacodynamics, dynamical brain measures and behavior. We hope this work paves the way for fruitful future work in this direction.

In summary, the present study used a novel, data-driven dynamical functional connectivity analysis (LEiDA) to investigate how psilocybin rapidly modulates the exploration of the brain's repertoire of functional network states under task-free conditions. We found a PL state closely corresponding to a canonical frontoparietal control system to be markedly destabilized by the compound, while transitions toward a globally coherent PL state were enhanced. We also found an increase in the metastability of global brain dynamics following the psilocybin infusion. Taken together, these findings are consistent with prior neuroimaging studies suggesting that a different type of brain integration and increased neural signal complexity underlie the psychedelic state. The present results also suggest that characterizing neuromodulatory effects on the brain's dynamical repertoire may help guide circuit-specific pharmacological interventions in neuropsychiatric disorders.

Abstract

Entropy is a dimensionless quantity that is used for measuring uncertainty about the state of a system but it can also imply physical qualities, where high entropy is synonymous with high disorder. Entropy is applied here in the context of states of consciousness and their associated neurodynamics, with a particular focus on the psychedelic state. The psychedelic state is considered an exemplar of a primitive or primary state of consciousness that preceded the development of modern, adult, human, normal waking consciousness. Based on neuroimaging data with psilocybin, a classic psychedelic drug, it is argued that the defining feature of "primary states" is elevated entropy in certain aspects of brain function, such as the repertoire of functional connectivity motifs that form and fragment across time. Indeed, since there is a greater repertoire of connectivity motifs in the psychedelic state than in normal waking consciousness, this implies that primary states may exhibit "criticality," i.e., the property of being poised at a "critical" point in a transition zone between order and disorder where certain phenomena such as power-law scaling appear. Moreover, if primary states are critical, then this suggests that entropy is suppressed in normal waking consciousness, meaning that the brain operates just below criticality. It is argued that this entropy suppression furnishes normal waking consciousness with a constrained quality and associated metacognitive functions, including reality-testing and self-awareness. It is also proposed that entry into primary states depends on a collapse of the normally highly organized activity within the default mode network (DMN) and a decoupling between the DMN and the medial temporal lobes (which are normally significantly coupled). These hypotheses can be tested by examining brain activity and associated cognition in other candidate primary states such as rapid eye movement (REM) sleep and early psychosis and comparing these with non-primary states such as normal waking consciousness and the anaesthetized state.

Keywords: serotonin, default mode network, criticality, entropy, 5-HT2A receptor, metastability, consciousness, REM sleep

Introduction

The main aim of this paper is to introduce a new theory of conscious states that incorporates principles of physics, neurobiology, and psychoanalysis. The theory is intended to assist our understanding of the makeup of the human mind, addressing such questions as: "how does the normal waking consciousness of healthy adult humans relate to other states of consciousness?" "how does the human brain maintain its normal state of waking consciousness?" and "what happens to the human brain's functionality when non-ordinary states such as rapid eye movement (REM) sleep/dreaming, early psychosis and the psychedelic state occur?"

At its core, the entropic brain hypothesis proposes that the quality of any conscious state depends on the system's entropy[1] measured via key parameters of brain function. Entropy is a powerful explanatory tool for cognitive neuroscience since it provides a quantitative index of a dynamic system's randomness or disorder while simultaneously describing its informational character, i.e., our uncertainty about the system's state if we were to sample it at any given time-point. When applied in the context of the brain, this allows us to make a translation between mechanistic and qualitative properties. Thus, according to this principle, increased subjective uncertainty or "puzzlement" accompanies states of increased system entropy. These ideas are consistent with Karl Friston's free-energy principle[2] and readers interested in Bayesian inference and the mechanisms by which the brain is hypothesized to minimize free-energy/surprise should consult this work (Friston, 2010).

System entropy, as it is applied to the brain, is related to another current hot-topic in cognitive neuroscience, namely "self-organized criticality"[3] (Chialvo *et al.*, 2007). The phenomenon of self-organized criticality refers to how a complex system (i.e., a system with many constituting units that displays emergent properties at the global-level beyond those implicated by its individual units) forced away from equilibrium by a regular input of energy, begins to exhibit interesting properties once it reaches a critical point in a relatively narrow transition zone between the two extremes of system order and chaos. Three properties displayed by critical systems that are especially relevant to the present paper are: (1) a maximum number of "metastable" or transiently-stable states (Tognoli and Kelso, 2014), (2) maximum sensitivity to perturbation, and (3) a propensity for cascade-like processes that propagate throughout the system, referred to as "avalanches" (Beggs and Plenz, 2003). There is growing evidence that brain activity, like much of nature, displays critical behavior (Beggs and Plenz, 2003) - and this raises some interesting questions: e.g., does the brain activity of healthy-adult-humans exhibit characteristics of criticality during normal waking consciousness, or are there other states of consciousness in which these characteristics are even more pronounced?

Another major topic that is covered in this paper is the psychoanalytic model of the structure of the mind (i.e., Freud's "metapsychology"). Specifically, we discuss some of the most fundamental concepts of Freudian metapsychology, with a special focus on the ego[4]. We focus on the ego because it is one of Freud's less abstract constructs and it is hypothesized that its disintegration is necessary for the occurrence of primary states. The ego can be defined as a sensation of possessing an immutable identity or personality; most simply, the ego is our "sense of self." Importantly however, in Freudian metapsychology, the ego is not just a (high-level) sensation of self-hood; it is a fundamental system that works in competition and cooperation with other processes in the mind to determine the quality of consciousness. It is because Freud described "the ego" in this mechanistic sense that it can be considered a useful complement to the more widely used concept of "the self." Effectively, the terms "ego" and "self" are synonyms, except that "the ego" has a background in Freudian metapsychology.

Finally, the shared topic that connects all of the above and offers a unique potential for their empirical study is the psychedelic drug state. In the following section we make the case that scientific research with psychedelics has considerable potential for developing aspects of psychoanalytic theory and for studying human consciousness more generally. Citing recent neuroimaging findings involving the classic psychedelic drug, psilocybin, the psychedelic state is described as a prototypical high-entropy state of consciousness (i.e., higher than normal waking consciousness). Intriguingly, we show evidence that the brain exhibits more characteristics of criticality in the psychedelic state than are apparent during normal waking consciousness. Moreover, this leads to the proposal that the brain of modern adult humans differs from that of its closest evolutionary and developmental antecedents because of an extended capacity for entropy suppression, implying that the system (i.e., the brain) gravitates away from criticality proper toward a state of slight sub-criticality. The psychological counterpart of this process is the development of a mature ego[5] and associated metacognitive functions (see below for relevant definitions of these terms). Specifically, we propose that within-default-mode network (DMN)[6] resting-state functional connectivity (RSFC)[7] and spontaneous, synchronous oscillatory activity in the posterior cingulate cortex (PCC), particularly in the alpha (8-13 Hz) frequency band, can be treated as neural correlates of "ego integrity." Evidence supporting these hypotheses is discussed in the forthcoming sections.

Before beginning it is important to address an initial point of potential ambiguity. The view taken here is that the human brain exhibits greater entropy than other members of the animal kingdom, which is equivalent to saying that the human mind possesses a greater repertoire of potential mental states than lower animals (see Giulio Tononi's information integration theory of consciousness cited below). Thus, if referring to human evolution beyond our closest *surviving* relatives then it would be misleading to suggest that entropy-suppression is the defining property of the human brain - indeed, it might be more accurate to speak of entropy-expansion. The evolution of human consciousness may have occurred through a process of relatively rapid entropy-expansion (with a concomitant increase in system disorder) followed by entropy-suppression (or system re-organization and settling). Thus, the proposal that normal waking consciousness in healthy, adult, modern humans depends on entropy suppression implies that there was a state relatively proximal to this (e.g., in archaic homo-sapiens and in infants) in which entropy was relatively elevated, as it is in primary states. The point is that the brain of adult modern-humans is in a settling rather than expanding phase.

The Research Value of Psychedelics

> "It does not seem to be an exaggeration to say that psychedelics, used responsibly and with proper caution, would be for psychiatry what the microscope is for biology and medicine or the telescope is for astronomy. These tools make it possible to study important processes that under normal circumstances are not available for direct observation." (Grof, 1980)

In 1953, the British research psychiatrist Humphrey Osmond was investigating the psychotomimetic (psychosis mimicking) effects of mescaline, a psychedelic drug derived from the peyote cactus. The British author Aldous Huxley learned of Osmond's work and struck up a correspondence, requesting that Osmond supervise a personal psychedelic experience. Huxley's subsequent mescaline experience would become the subject of his famous book "*The Doors of Perception*" (Huxley, 1954). Like many before and after him, Huxley was profoundly affected by his experiences with psychedelics and in 1956 sought with Osmond a satisfactory term for this class of drugs. At the time, "psychotomimetics" and "hallucinogens" were popular, but both men felt that these referred to mere aspects of the drug experience and not its essential character. Huxley suggested "phanerothyme," intending to mean "bringing forth the spirit or soul" (Huxley *et al.*, 1977), and Osmond offered "psychedelic" combining the Greek words for "mind" or "soul" (psyche) with "dclôs&emacr;," meaning "to manifest." While it was Osmond's "psychedelic" that would stick, it is telling that both men were searching for a word that could denote the same essential property, i.e., psychedelic's ability to make manifest latent aspects of the mind.

In 1943, Swiss chemist Albert Hofmann discovered the extraordinary psychological properties of lysergic acid diethylamide (LSD) (Hofmann, 1980) and the first reports on its effects appeared in scientific journals in the late 1940s. These papers immediately highlighted LSD's potential to be psychologically agitative. The first English language publication was released in 1950 and here the authors reported: "*the effect of LSD was a transitory toxic state, disturbing the barrier of repression and permitting a re-examination of significant experiences of the past that were sometimes relived with a frightening realism.*" (Busch and Johnson, 1950) In the following years, psychedelics became one of the most researched classes of psychoactive drug in science, with several hundred relevant publications (Grinspoon and Bakalar, 1979). During these years, the focus shifted from psychedelics as psychotomimetics to psychedelics as psychotherapeutic adjuncts, with major international conferences on the topic (Grinspoon and Bakalar, 1979) and even the construction of purpose-built psychedelic treatment centers (Sandison, 2001). Political pressure in the late 1960s led to the illegalization of psychedelics and this had a significant negative impact on legitimate scientific research (Grinspoon and Bakalar, 1979; Lee and Shlain, 1985) - a problem that continues today (Nutt *et al.*, 2013). Despite this however, there has been a resurgence of scientific interest in psychedelics in recent years (Vollenweider *et al.*, 1998; Nichols, 2004; Griffiths *et al.*, 2006, 2008; Moreno *et al.*, 2006; Gonzalez-Maeso *et al.*, 2007; Grob *et al.*, 2011; Carhart-Harris *et al.*, 2012a).

The dominant theoretical and therapeutic approach during the early era of psychedelic research was psychoanalytic. Psychedelics were used therapeutically under the rationale that they work to lower psychological defenses to allow personal con- flicts to come to the fore that can then be worked through with a therapist (Cohen, 1972). A related model was that the relinquishment of "ego" enabled profound existential or "peak" experiences to occur that could have a lasting positive impact on behavior and outlook (Savage, 1962). Innumerable cases of apparent spontaneous insights about "self" or "nature" exist in the literature on psychedelics (Cattell, 1954; Sandison, 1954; Sandison and Whitelaw, 1957; Denber, 1958; Hausner and Dolezal, 1965; Torda, 1969; Cohen, 1972; Grof, 1982) and reports of "ego-dissolution" or "disintegration" are commonplace among those who have experienced the effects of these drugs (Carhart-Harris and Nutt, 2010; Carhart-Harris *et al.*, 2012b). Some psychiatrists even believed that psychedelics could provide the necessary scientific evidence for major psychoanalytic hypotheses (Sandison, 1954; Cohen, 1972; Grof, 1982). For example, one enthused: "*The phenomenology of the psychodynamic experiences in LSD sessions is to a large extent in agreement with the basic concepts of classical psychoanalysis … Observations from LSD psychotherapy could be considered laboratory proof of the basic Freudian premises.*" (Grof, 1982).

Psychoanalytic theory dominated psychiatry in the 1950s but after influential critiques (Eysenck, 1973), the cognitive revolution (Neisser, 1967) and significant pharmacological developments in psychiatry (Ban, 2001a,b; Fink, 2010), its influence significantly waned. As illustrated in **Figure 1**, despite over a century since its inception, psychoanalysis has failed to establish itself as a science of the mind. This may be because its hypotheses are hollow (Webster, 1995) or because they do not easily lend themselves to controlled experiment. In contrast, cognitive psychology is a mechanistic framework for describing observable phenomena that has become the natural bedfellow for human neuroscience. In comparison with the spectacular success of cognitive psychology, what should we make of the relative stagnancy of psychoanalysis? Is psychoanalysis scientifically redundant? Its fiercest critics claim that it is a belief system, a tautology with untestable hypotheses (Webster, 1995) but others claim that it has considerable explanatory value but could benefit from a closer integration with cognitive neuroscience (Kandel, 1999; Carhart-Harris and Friston, 2010; Panksepp and Solms, 2012). The present article takes this latter view and argues that the most realistic way forward for psychoanalysis as a science is for its most tangible hypotheses to be simplified and applied within the framework of cognitive neuroscience. Here we take the view that this is a necessary concession for psychoanalysis if it is to develop its credibility as a model of the mind.

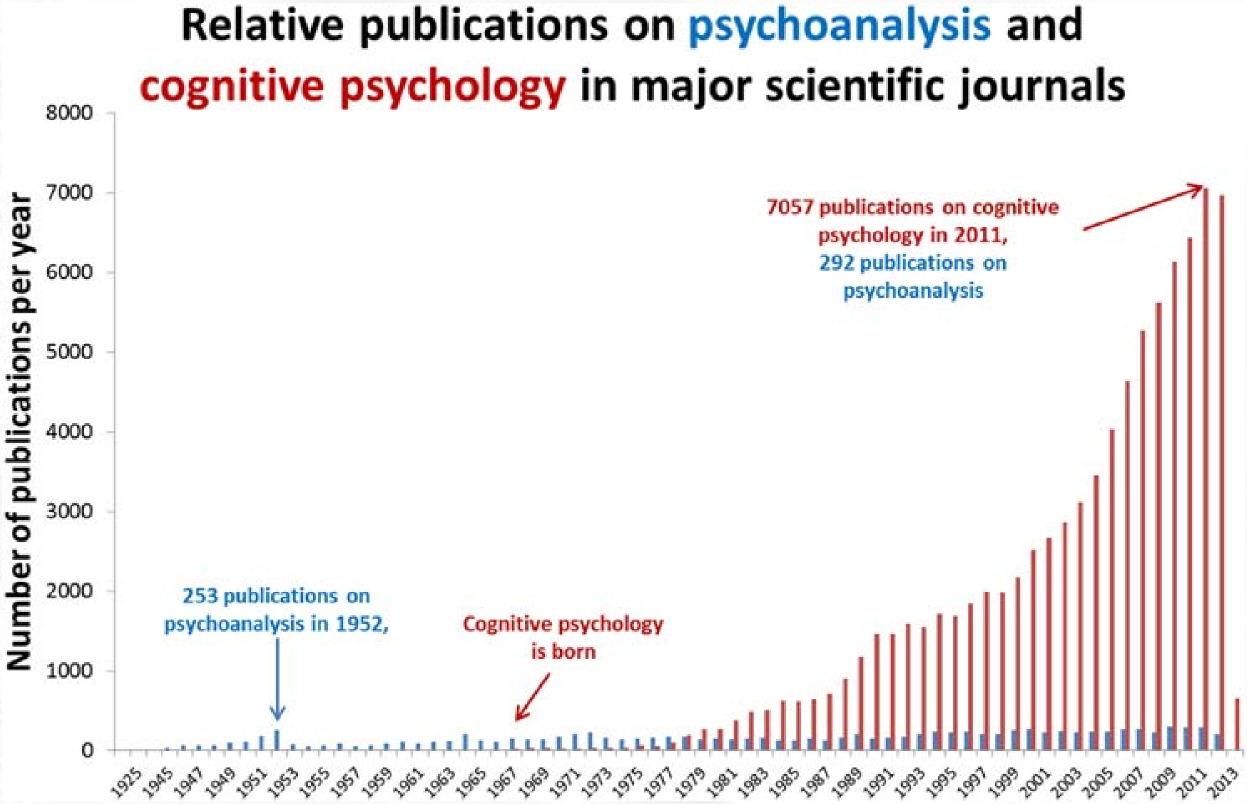

FIGURE 1 - Relative publications on psychoanalysis and cognitive psychology. Annual publications in major medical science journals referenced in the leading database, PubMed. Articles were retrieved by entering the search terms "psychoanalysis" and "cognitive psychology" in separate searches using the default search parameters of PubMed. It is worth noting that psychoanalysis has a different publication culture to cognitive neuroscience. Articles on psychoanalysis are not always available via PubMed and many psychoanalytic writings are published in books rather than academic journals. With these caveats entered however, the publication count shown above still helps to illustrate the general point that psychoanalysis has failed to gain a significant foothold in mainstream analytical science.

In what follows, a roadmap is presented for how scientific research with psychedelics can assist the integration of psychoanalysis with cognitive neuroscience in order to further our understanding of human consciousness. This is motivated by the view that psychoanalysis can contribute something substantial to the mind sciences because it bridges an explanatory gap that has been left vacant by cognitive psychology. This gap only exists because cognitive psychology (rightly) focuses on phenomena that can be observed and manipulated by controlled experiment but crucially, *without psychedelic drugs, it is virtually impossible to bring the core phenomena of psychoanalytic theory into an observable space*.

Freud famously said of dreams that they provide privileged access to the workings of the unconscious mind (Freud, 1937) but research on dreaming is fraught with difficulties because [despite the phenomenon of lucid dreaming (Ogilvie *et al*., 1982)] the dream experience cannot be easily reflected on and reported in real-time, and neither can its onset and offset be easily controlled. Thus, Freud's cherished "royal road" has not proved particularly regal and a more practical alternative is required if key psychoanalytic theories are to be incorporated into the mind sciences.

> "If, as Freud said, dreams are the royal road to the unconscious, is it possible that psychedelic drugs are a superhighway to the unconscious?" (Holden, 1980)

This article argues that controlled studies with psychedelics are capable of providing major new insights into the nature of the mind and how it arises from brain activity. This is because the mind must be thoroughly deconstructed in order for us to become cognizant of its constituents and how they interact to give rise to global phenomena. The unique scientific value of psychedelics rests on their ability to selectively target processes that appear to be critical for the maintenance of normal waking consciousness. In addressing the action of psychedelic drugs on the brain, this article begins at the cellular level before progressing to the systems level. The intention is to offer a comprehensive account of how psychedelics alter brain function to alter consciousness.

Somewhat uniquely, psychedelics can be studied at a range of epistemological levels; from molecular pharmacology (Gonzalez-Maeso and Sealfon, 2009) to psychoanalytic psychology (Cohen, 1964; Grof, 1982), few topics can engage scientists from as wide a range of disciplines. This reflects not only the special research value of psychedelics but also the immensity of the challenge involved in understanding them; especially, if the intention is to develop a comprehensive account of how psychedelics affect the brain to alter consciousness. The present article should therefore be read with an acknowledgement that this quest is on-going.

Before we begin, it is necessary to enter some important caveats. Firstly, it needs to be stated that those looking for evidence for the authenticity of aspects of Freudian theory will be left dissatisfied by this article. Categorically, this is not its aim. This challenge requires a thorough review of the phenomenology of relevant altered states of consciousness (e.g., the psychedelic state) and this is something that has been attempted before (Carhart-Harris, 2007; Carhart-Harris and Friston, 2010). Thus, due to space limitations, this article's treatment of the relevant phenomenology is relatively superficial. Instead it places its focus on the system-level mechanics of the psychedelic state as an exemplar of a regressive[8] style of cognition that can also be observed in REM sleep and early psychosis.

Some proponents of psychoanalysis may feel that this mechanistic approach has little relevance to psychoanalysis in its hermeneutic or interpretative guise. However, the inherent subjectivity of this aspect of psychoanalysis means that it is difficult to see how it can ever significantly impinge on the scientific study of the mind and brain. Indeed, Freud acknowledged that it was his "metapsychology" that had the most to offer science (Freud, 1949), and at least as a first step, this is where psychoanalytic theory (rather than psychoanalytic practice) should look to develop its scientific credibility. Briefly, for readers who are unfamiliar with Freudian metapsychology and wish to understand it better, his original material should be read (e.g., Freud, 1927, 1949; Freud *et al.*, 1957) and the following review articles may be useful (Carhart-Harris *et al.*, 2008; Carhart-Harris and Friston, 2010). For those interested in the rich phenomenology of the psychedelic experience and how this relates to Freudian and/or Jungian descriptions of "the unconscious mind," the following references may be of interest (Sandison and Whitelaw, 1957; Huxley, 1959; Cohen, 1964; Grof, 1982; Merkur, 1998; Sandison, 2001). Lastly, it is necessary to state that questions related to the safety of scientific research with psychedelics will not be addressed here. However, evidence strongly supports the position that, conducted with appropriate caution, research with psychedelics presents a low risk of harm to study participants (Johnson *et al.*, 2008; Morgan *et al.*, 2010; Carhart-Harris and Nutt, 2010; Studerus *et al.*, 2011; van Amsterdam *et al.*, 2011).

The Pharmacology of Psychedelics

Before introducing the focal topic of this paper, i.e., entropy and its relation to key brain imaging parameters, it is important to provide a brief introduction to the pharmacology of psychedelics. By definition, all classic psychedelic drugs are agonists at the serotonin 2A receptor (5-HT_{2A}R) (Glennon *et al.*, 1984). There is a strong positive correlation between a psychedelic's affinity for the 5-HT_{2A}R and its psychedelic potency (Glennon *et al.*, 1984). For example, LSD has a very high affinity for the 5-HT_{2A}R and is remarkably potent, being psychoactive in doses as small as 20µM (Hintzen and Passie, 2010). Blockade of the 5-HT_{2A}R with the 5-HT_{2A}R antagonist ketanserin, attenuates the principal hallucinogenic effects of psilocybin in humans (Vollenweider *et al.*, 1998). The 5-HT_{2A}R is primarily expressed in the cortex (Pazos *et al.*, 1987). In humans, the distribution of 5-HT_{2A}Rs is generally high throughout the cortex but is densest in high-level association regions such as the

PCC and lowest in the primary motor cortex (Erritzoe *et al*., 2009; Carhart-Harris *et al*., 2012a). This may explain why cognition and perception are so markedly affected by psychedelics whereas motor action is generally not. In terms of the cortex's laminar organization, 5-HT_{2A}Rs are most densely expressed post-synaptically on the apical dendrites of layer 5 pyramidal neurons (Weber and Andrade, 2010). These large excitatory neurons are the primary source of output from a cortical region, projecting to hierarchically subordinate cortical and subcortical regions (Spruston, 2008). 5-HT_{2A}R stimulation depolarizes the host cell, making it more likely to fire (Andrade *et al*., 2011) and this effect has been demonstrated in layer 5 pyramidal neurons in rodents (Aghajanian and Marek, 1997).

Functional MRI and MEG Studies with Psilocybin

Beginning in 2009, our research team embarked on a series of studies with the classic psychedelic, psilocybin (Carhart-Harris *et al*., 2012a), culminating in a recent MEG study (Muthukumaraswamy *et al*., 2013). Our first study utilized arterial spin labeling (ASL), an fMRI technique that measures changes in CBF. Specifically, we compared CBF before and after intravenous (i.v.) administration of 2 mg psilocybin and placebo (Carhart-Harris *et al*., 2012a). The onset of the subjective effects of psilocybin is rapid when it is administered intravenously, commencing within seconds of the end of the infusion (Carhart-Harris *et al*., 2011). The infusion occurred over 60 s, beginning 6 min into an 18 min resting state scan. Drug-induced changes in CBF were modeled based on psilocybin's rapid pharmacodynamics (Carhart-Harris *et al*., 2011). Fifteen healthy volunteers were scanned and the results revealed decreased CBF after psilocybin and no increases. The decreases were localized to high-level association cortices, including key regions of the DMN (see Some background on the default mode network (DMN) for an overview of this system) and subcortical hub structures such as the putamen and thalamus (Carhart-Harris *et al*., 2012a).

These findings were later replicated using the classic BOLD signal of fMRI. Another 15 healthy volunteers were scanned using a similar placebo-controlled design, with 60 s i.v. infusions beginning midway through two separate 12 min eyes-closed resting state scans on different days. Again, only signal decreases were observed after drug infusion. Moreover, the location of the BOLD signal decreases was consistent with the CBF decreases, e.g., in midline cortical nodes of the DMN (Muthukumaraswamy *et al*., 2013).

In addition to modeling changes in the direction of the BOLD signal post-infusion of psilocybin, we also measured changes in brain network integrity using resting-state functional connectivity. Three regions of interest were chosen for separate seed-based resting state functional connectivity (RSFC) analyses: a medial prefrontal cortex (mPFC) seed, a right middle frontal gyrus (mFG) seed, and a bilateral hippocampal seed. Decreased connectivity was observed within the DMN using the mPFC and hippocampal seeds and in a major task-positive network (TPN), the dorsal attention network (DAN), using the mFG seed (**Figure 2**).

In our third and most recent study, we used MEG to investigate the effects of psilocybin on neural activity. Broadband decreases in oscillatory power were observed after psilocybin, and again, these were localized to association cortices, including key regions of the DMN, such as the PCC (Raichle *et al*., 2001; Greicius *et al*., 2003) **- see Figure 2**.

These studies provide some useful clues about the mechanisms by which psychedelics alter brain function to alter consciousness. They imply that cerebral blood flow, BOLD signal, functional connectivity and oscillatory power are decreased in brain regions that are normally highly metabolically active, functionally connected and synchronous/organized in their activity. These results provided the kernel for our subsequent thinking about increased entropy in the psychedelic state. Although none of the analyses formally measured entropy, they spoke to a general principle that psychedelics alter consciousness by *disorganizing* brain activity.

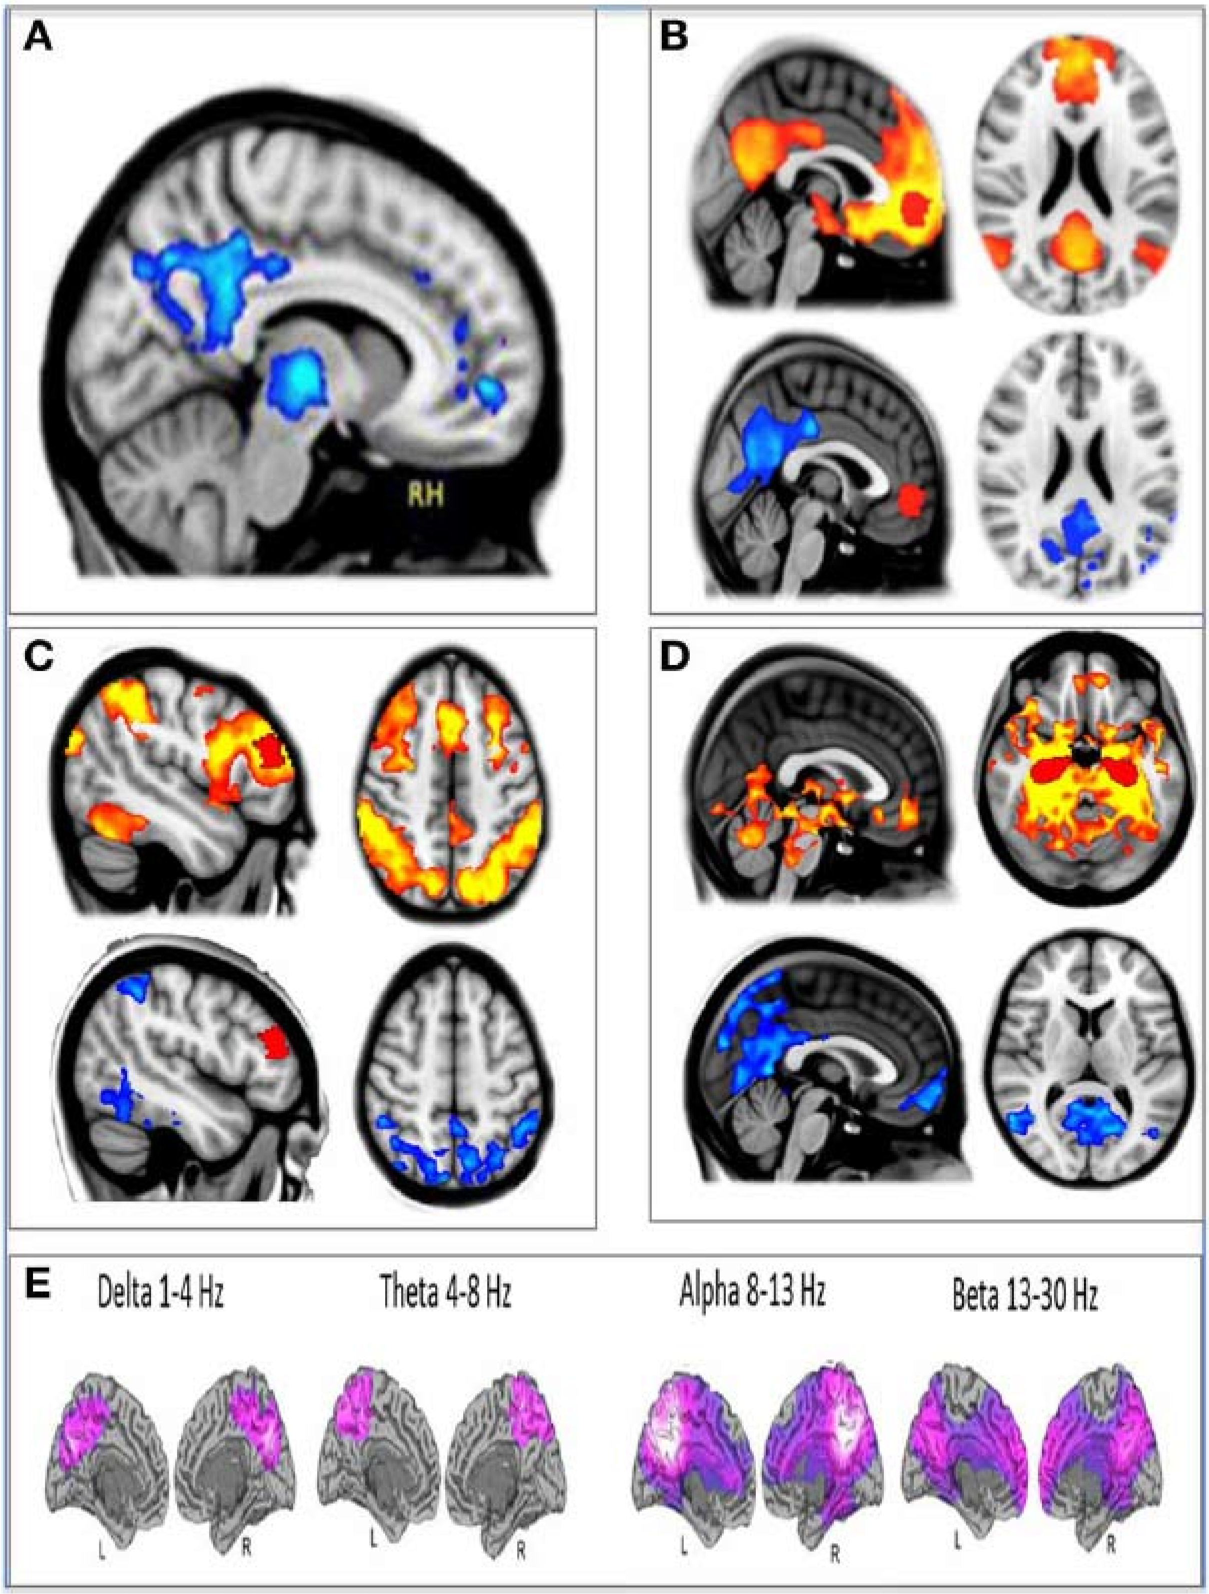

FIGURE 2 - **The effect of psilocybin on fMRI and MEG measures of brain activity**. **(A)** Decreased CBF post-psilocybin. **(B)** Ventromedial PFC (red) resting state functional connectivity (RSFC) at baseline (top, orange) and decreases post-psilocybin (bottom, blue). **(C)** Dorsolateral PFC (red) RSFC at baseline (top, orange) and decreases post-psilocybin (bottom, blue). **(D)** Hippocampal (red) RSFC at baseline (top, orange) and decreases post-psilocybin (bottom, blue). **(E)** Decreases in oscillatory power (purple) post-psilocybin measured with MEG. All spatial maps were whole-brain cluster corrected $Z > 2.3$. $p < 0.05$.

Some Background on the Default Mode Network

The DMN has become one of the most discussed topics in cognitive neuroscience over the last decade and there are several reasons why it is justified to consider it important (Guldenmund *et al*., 2012). DMN regions receive more blood flow (Zou *et al*., 2009) and consume more energy (Raichle and Snyder, 2007) than other brain regions. Indeed, CBF and metabolic rate are approximately 40% higher in the PCC than the average of the rest of the brain (Raichle *et al*., 2001). The magnitude of the DMN's energy consumption dwarfs the comparatively trivial energy changes induced by stimulus cues (Raichle, 2006, 2010). DMN regions are centers of dense connectivity (Hagmann *et al*., 2008),implying that they serve as important connector hubs for information integration and routing (van den Heuvel *et al*., 2012). Consistent with this, a major node of the DMN, the PCC, can be spatially segmented into sub-components that functionally couple to different brain networks (Leechetal.,2012). Similarly,during transient windows of especially high internal coupling (functional connectivity) within the DMN, coupling between the DMN and other brain networks is also markedly increased (de Pasquale *et al*., 2012). Importantly, this functional centrality of the DMN is not shared by other brain networks (de Pasquale *et al*., 2012; Braga *et al*., 2013), implying that, as the highest level of a functional hierarchy (Carhart-Harris and Friston, 2010), it serves as a central *orchestrator* or *conductor* of global brain function. Functionally, the DMN is relatively removed from sensory processing (Sepulcre *et al*., 2012) and is instead engaged during higher-level, metacognitive operations such as self-reflection (Qin and Northoff, 2011), theory-of-mind (Spreng and Grady, 2010) and mental time-travel (Buckner and Carroll, 2007) - functions which may be exclusive to humans. DMN connectivity increases through development from birth to adulthood (Fair *et al*., 2008; Gao *et al*., 2009) and DMN regions have undergone significant evolutionary expansion (Van Essen and Dierker, 2007). Despite our knowledge of these things however, it is poorly understood why the DMN consumes so much of the body's energy (Raichle and Mintun, 2006). This uncertainty regarding the nature of the DMN's disproportionate energy consumption has led to loose analogies being made between it and the *dark energy* of cosmology (Raichle, 2006, 2010). It is consistent with the hypotheses of this paper to suggest that this apparent excess energy of apparently unknown function, residing in the DMN, is in fact the physical counterpart of the narrative-self or ego - much of which is indeed unconscious or implicit.

Introducing Primary Consciousness and Primary States

This article proposes that states such as the psychedelic state, REM sleep, the onset-phase of psychosis and the dreamy-state of temporal lobe epilepsy are examples of a regressive style of cognition that is qualitatively different to the normal waking consciousness of healthy adult humans. We will refer to this mode of cognition as "primary consciousness"[9] and the states themselves as "primary states." To enter a primary state from normal waking consciousness, it is proposed that the brain must undergo a "phase transition" (Zeeman, 1973; Waddington, 1974), just as there must have been a phase-transition in the evolution of human consciousness with the relatively rapid development of the ego and its capacity for metacognition[10]. This implies that the relationship between normal waking consciousness and "primary consciousness" is not perfectly continuous.

Freud was a great admirer of Darwin and made several references to him throughout his work (Freud *et al*., 1953). Indeed, Freud considered his own hypotheses to be natural deductions from evolutionary theory. He argued that dreaming and psychosis typify a primitive style of thinking that is dominant in human infancy[11] and dominated the cognition of primordial man[12], preceding the development of the ego of modern adult humans. Primitive thinking is fundamentally different to the style of cognition possessed by healthy adult humans. This is because in healthy adults, the formation of a mature ego endows the mind with a capacity for metacognition i.e., an ability to reflect on one's own thoughts and behavior (Shimamura, 2000; Fleming *et al*., 2012).

These ideas form the core of this article's hypotheses. Thus, it is appropriate to clarify them here. A distinction is being made between two fundamentally different styles of cognition, one that is associated with the consciousness of mature adult humans, and another that is a mode of thinking the mind regresses to under certain conditions, e.g., in response to severe stress, psychedelic drugs and in REM sleep. The style of cognition that is dominant in normal waking consciousness will henceforth be referred to as *secondary consciousness*[13] and the (pre-ego) style of cognition that is associated with primitive states will be referred to as *primary consciousness*. It is acknowledged that these terms have been used before (Edelman, 2004) but their meaning in the present context is largely independent.

Consistent with Karl Friston's free-energy principle (Friston, 2010), this article takes the view that the mind has evolved (via secondary consciousness upheld by the ego) to process the environment as *precisely* as possible by finessing its representations of the world so that *surprise* and *uncertainty* (i.e., entropy) are minimized. This process depends on the ability of the brain to organize into coherent, hierarchically-structured systems (Bassett *et al.*, 2008; Friston, 2010), critically poised between order and disorder (Friston *et al.*, 2012b; Schwartenbeck *et al.*, 2013). In contrast, in primary states, cognition is less meticulous in its sampling of the external world and is instead easily biased by emotion, e.g., wishes and anxieties.

Later we finesse this basic model, arguing that secondary consciousness actually depends on the human brain having developed/evolved a degree of sub-criticality in its functionality, i.e., an extended ability to suppress entropy and thus organize and constrain cognition. It is argued that this entropy-suppressing function of the human brain serves to promote realism, foresight, careful reflection and an ability to recognize and overcome wishful and paranoid fantasies. Equally however, it could be seen as exerting a limiting or narrowing influence on consciousness.

This paper argues that the underlying neurodynamics of primary states are more "entropic" than secondary states i.e., primary states exhibit more pronounced characteristics of criticality and perhaps supercriticality than normal waking consciousness - implying that the latter is slightly sub-critical, if not perfectly critical. Secondary consciousness pays deference to reality by carefully sampling the world and learning from its encounters (Friston, 2010), whereas primary consciousness does this more haphazardly. Mechanistically, whereas the brain strives toward organization and constraint in secondary consciousness, processes are more flexible in primary consciousness. Freud outlined these ideas in his writings on "the reality principle" (Freud, 1927) and they are recast here in a more mechanistic form, tied to modern cognitive neuroscience.

The phenomenon of "magical thinking"[14] (Frazer, 1900; Subbotskii, 2010; Hutson, 2012) is a potential product of primary consciousness. Magical thinking is a style of cognition in which supernatural interpretations of phenomena are made. Magical thinking is more likely in situations of high uncertainty because there is a greater opportunity for dreaming up explanations that lack an evidence base (Friston, 2010). Wishful beliefs are a classic product of magical thinking because they interpret the world according to what an individual *wants* to be true (in Freudian terms, they adhere to the pleasure principle). Wishful inferences are quick-fixes that reduce uncertainty but via simplistic explanations that satisfy fancies or desires before careful reason. Another example of magical thinking is paranoia; in this case, an individual jumps to negative conclusions about a situation, even in the face of contradictory evidence, because to do so effectively suspends uncertainty while providing some narcissistic satisfaction. The popularity of magical thinking also suggests that there is some enjoyment in uncertainty, perhaps because it promotes imaginative and creative thinking - and that this is associated with positive affect.

In the forthcoming section we discuss the relationship between medial temporal lobe (MTL - i.e., specially the hippocampus and surrounding parahippocampal structures) activity and primary consciousness, highlighting a specific change in activity that may serve as a marker of primary states.

The Medial Temporal Lobes and Primary Consciousness

Recording directly from MTL circuits in different altered states presents a significant challenge for cognitive neuroscience, but not one that should deter us from trying to expand its reach into areas of relevance to psychoanalytic theory. Pioneering surgical interventions for epilepsy and Alzheimer's disease (Axmacher *et al.*, 2008, 2010; Fell *et al.*, 2011, 2012; Laxton and Lozano, 2012) are opening up new possibilities for depth recordings, and although it would be a challenge to defend the administration of psychedelics to such patients, recording from MTL circuits in other primary states, such as REM sleep, might be more feasible (Cantero *et al.*, 2003).

Another way to circumvent the problem of recording directly from limbic regions is to use non-invasive imaging with high spatial resolution. We recently used fMRI to investigate the involvement of the MTLs in the mechanism of action of psychedelics, performing a hippocampal functional connectivity analysis using the same psychophysiological interaction (PPI) model used in our previous analyses with psilocybin (Carhart-Harris *et al.*, 2012a). A combined bilateral hippocampal and parahippocampal mask was created on a standard brain and time-series were extracted from these regions for each subject and regressed against their functional data, with the pharmacodynamics of intravenous psilocybin modeled as an interaction term. Remarkably, decreases in functional coupling were observed after psilocybin that were selectively localized to the cortical nodes of the DMN (**Figure 2D**), entirely consistent with the hypothesis that decreased MTL-DMN coupling underlies phase transitions to primary consciousness.

In a separate analysis, we looked at changes in BOLD signal variance (i.e., amplitude fluctuations) after psilocybin and found significant increases in variance that were almost exclusively localized to the bilateral hippocampi and parahippocampal gyri. This result was important because it reinforced the impression given by the RSFC analysis that under psilocybin, the hippocampi become decoupled from the DMN. However, perhaps even more interestingly, the increase in MTL signal variance was consistent with some early depth electrode work with psychedelics that implicated the MTLs in their mechanism of action. This work is reviewed below.

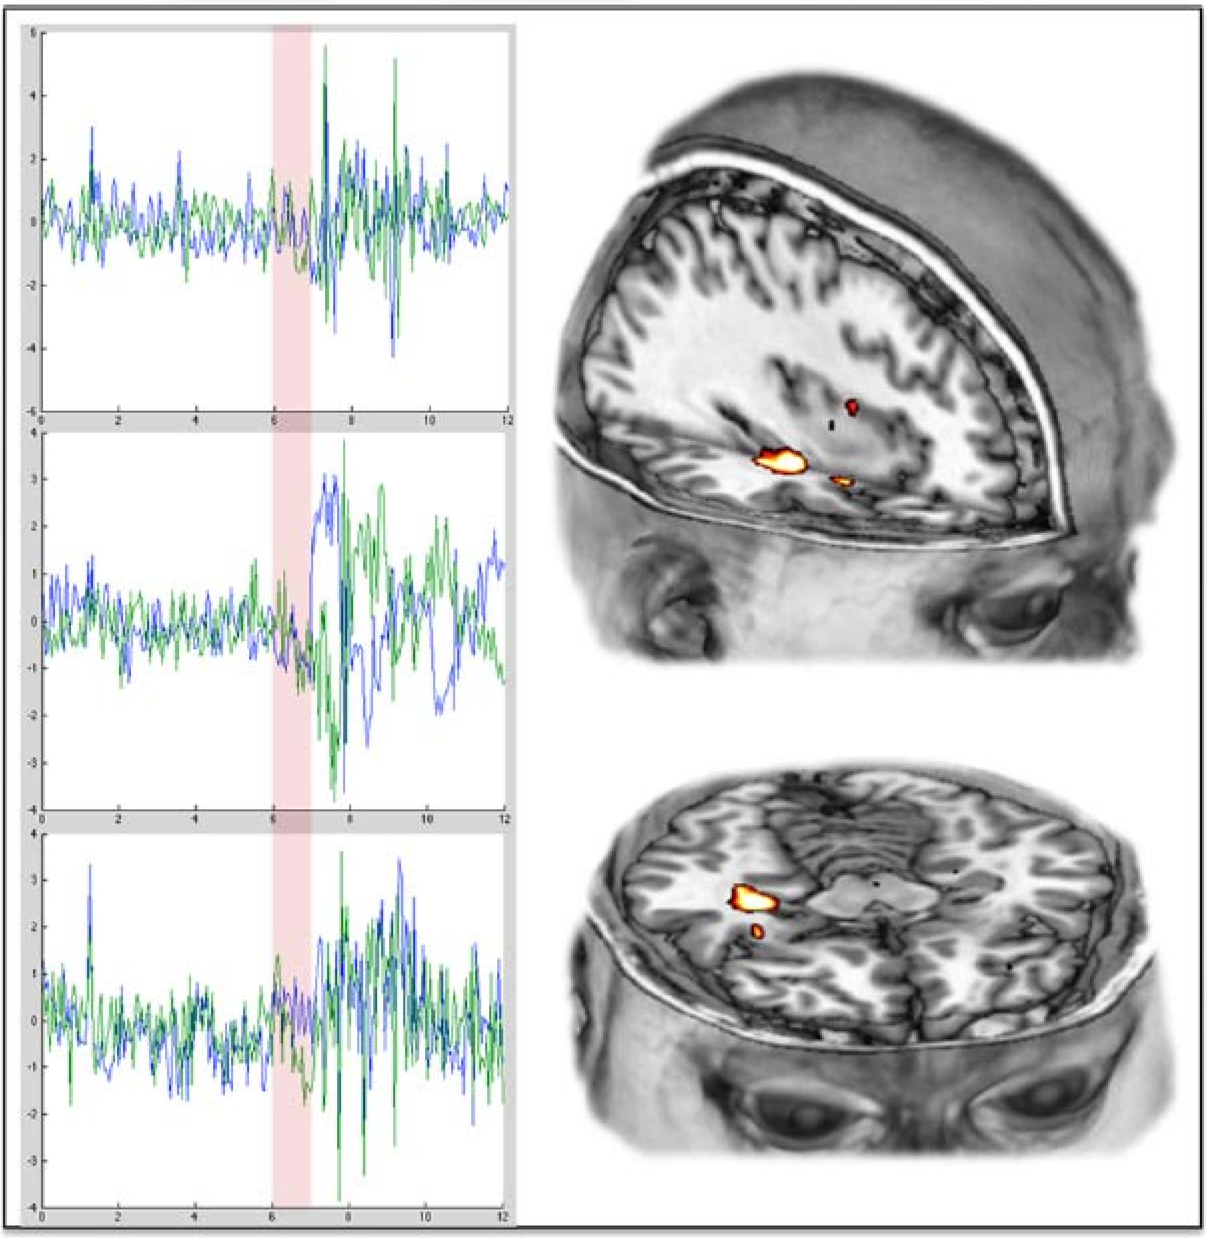

FIGURE 3 - Increased variance/amplitude fluctuations in the hippocampus post-psilocybin. The charts on the **left** show the complete time series from the hippocampus (**left** in blue, **right** in green) in 3 different individual subjects during the 12 min scan in which they received psilocybin. The transparent red vertical line indicates the beginning and duration of the 60 s infusion of psilocybin. The images on the **right** show the **right** hippocampal region where the increases in variance were especially marked.

Human depth recordings involving the insertion of electrodes into structures located deep in the brain (Ramey and O'Doherty, 1960) were not uncommon in the 1950s and 60s. Remarkably, some intracranial recordings were carried out during this period in individuals administered LSD and mescaline (Schwarz *et al.*, 1956; Monroe *et al.*, 1957; Monroe and Heath, 1961). The relevant reports document unusual phasic activities in the MTLs during the drug state that were difficult to detect at the scalp. Moreover, in separate studies, temporal lobectomy was found to abolish the effects of LSD in humans (Serafetinides, 1965) and chimpanzees (Ramey and O'Doherty, 1960) and frontal lobotomy was found to augment them (Keup, 1970). Further support for the involvement of MTLs in the mechanism of action of psychedelics comes from reports of similar phasic limbic activity in other altered states of consciousness that show phenomenological similarities with the psychedelic state, namely: REM sleep, acute psychosis and the so-called "dreamy-state" of temporal lobe epilepsy and electrical stimulation of the MTL (Carhart-Harris, 2007; Carhart-Harris and Friston, 2010). Importantly, these states are all characterized by a particular style of cognition that is fundamentally different from that of normal waking consciousness.

It is proposed here that coupling between the MTLs and the cortical regions of the DMN is necessary for the maintenance of adult normal waking consciousness, with its capacity for metacognition. Moreover, a breakdown in hippocampal-DMN coupling is necessary for a regression to primary consciousness. These hypotheses are motivated by our finding that DMN-hippocampal coupling is decreased under psilocybin (**Figure 3D**), and while DMN activity becomes desynchronous and therefore disorganized (**Figure 3E**), the amplitude of BOLD signal fluctuations increases in the hippocampus (**Figure 2**).

The Default Mode Network and the Ego

Layer 5 pyramidal neurons densely express 5-HT$_{2A}$ receptors (Weber and Andrade, 2010). These cells are an important target of psychedelics (Aghajanian and Marek, 1997) and are known to fire with an intrinsic alpha frequency (Silva *et al.*, 1991; Sun and Dan, 2009). Alpha oscillations are thought to be related to temporal framing in perceptual processing (Lorincz *et al.*, 2009; Klimesch *et al.*, 2011) but more intriguingly given the focus of the present article, a positive relationship has been found between self-reflection and alpha power (Knyazev *et al.*, 2011) and alpha synchronization during rest and Blood Oxygen Level Dependent (BOLD) activity in regions of the DMN (Jann *et al.*, 2009). Evidence implicates the DMN in self-reflective and introspective functions (Qin and Northoff, 2011) and the phase of fluctuating activity in the DMN is often inversely correlated (or "anticorrelated") with fluctuating activity in networks concerned with task-focused attention (task-positive networks, TPNs) (Fox *et al.*, 2005). Like the DMN, alpha oscillations mature developmentally and evolutionarily (Basar and Guntekin, 2009), tempting speculations that these rhythms have developed to reduce "entropy" [i.e., disorder or uncertainty (Ben-Naim, 2008)] by increasing mutual information among neuronal ensembles (Tononi *et al.*, 1994; Basar and Guntekin, 2009). With this in mind, it was remarkable that we recently found a highly significant positive correlation between the magnitude of alpha power *decreases* in the PCC after psilocybin and ratings of the item "I experienced a disintegration of my 'self' or 'ego'." Scores on this item also correlated positively with decreases in delta, theta, beta, and low gamma power, although alpha explained the most variance (a considerable 66%) see **Figure 4**. Twenty three subjective items 2012). Theta oscillations are a canonical rhythm of hippocampal circuits, at least in rodents (Buzsaki, 2002), and MTLs are known to be strongly connected to the PCC (Parvizi *et al.*, 2006) and DMN more generally (Kahn *et al.*, 2008). Thus, it is feasible that a function of PCC theta oscillations is to constrain the activity of limbic circuits, which reciprocally input to the PCC. Evidence that MTL activity exerts a *driving* influence on PCC activity comes from a recent report on deep brain stimulation for Alzheimer's disease. Chronic stimulation of the fornix, an important component of hippocampal circuitry, was associated with significantly increased glucose metabolism in the PCC (Laxton *et al.*, 2012).

In summary, interaction between different oscillatory rhythms introduces a structured quality to brain activity (Rumsey and Abbott, 2004), constraining the naturally stochastic firing of individual pyramidal neurons (Rolls and Deco, 2010) and so providing ideal conditions for the emergence of "complexity" (Tononi *et al.*, 1994) or "self-organized criticality" (Jensen, 1998). A key hypothesis of this article is that it is through the development of self-organized activity in the DMN [and concomitant entropy/uncertainty/disorder minimization (Friston, 2010)] that a coherent sense of self or "ego" emerges (Carhart-Harris and Friston, 2010). This process of maturational settling succeeds an earlier state of elevated entropy (primary consciousness) and psychedelic drugs induce a regression to this entropic brain state via the mechanisms outlined above.

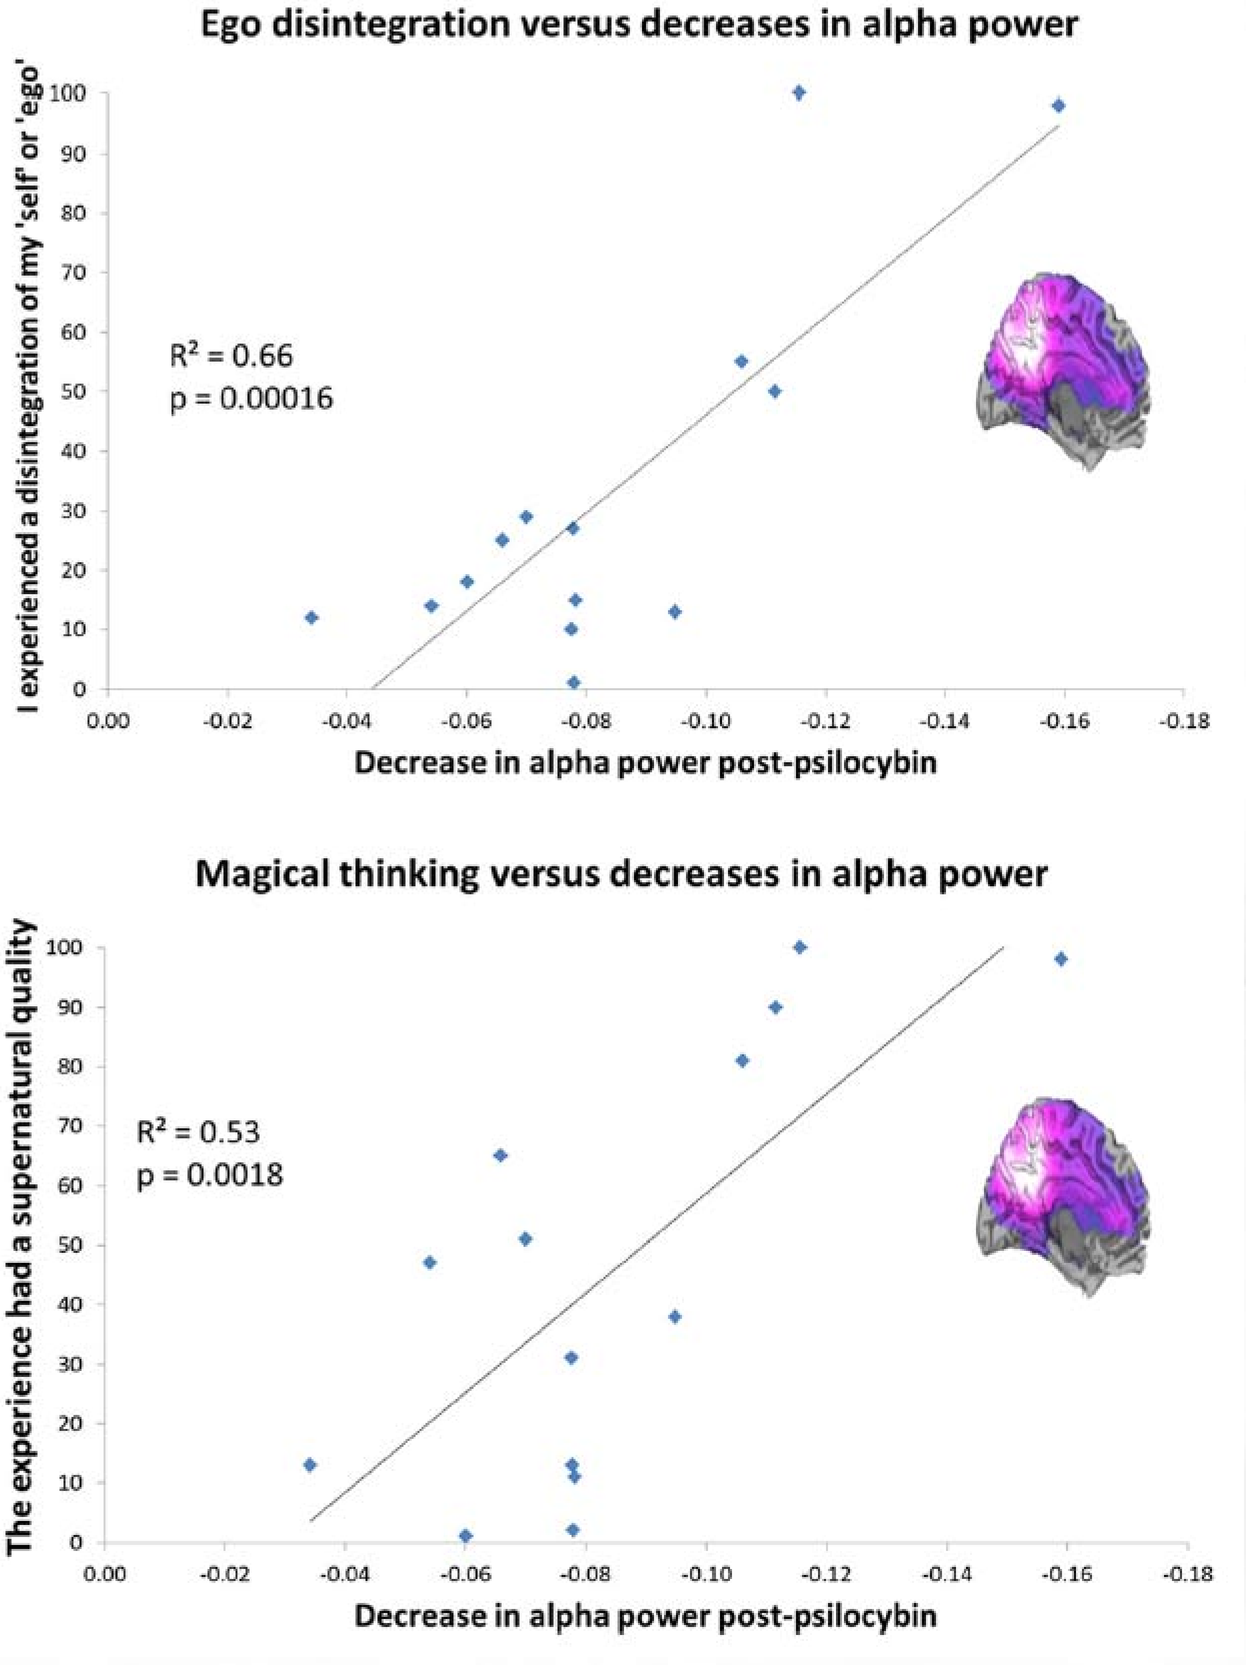

FIGURE 4 - **Decreased PCC alpha power predicts ego-disintegration and magical thinking after psilocybin. Top**: Decreased PCC alpha power vs. ratings of ego-disintegration. **Bottom**: Decreased PCC alpha power vs. ratings of magical/supernatural thinking. Both correlations were significant after correction for multiple comparisons (0.05/23 = 0.002). These charts are derived from data discussed in Muthukumaraswamy *et al*. (2013).

With these foundations laid, the following hypotheses can be proposed: (1) coupling within the DMN, and *especially* between the MTL and DMN, is a characteristic of maturational settling that is necessary for secondary consciousness and the development of an integrated sense of self; (2) a relative decoupling within the DMN and specifically between the MTLs and DMN occurs when secondary consciousness abates and there is a reciprocal increase in the influence of primary consciousness; (3) decreased MTL-DMN coupling allows the

MTLs to function more independently of the DMN and this can result in unusual MTL activities such as have been recorded with depth electrodes in primary states (see above and Grof, 1982; Bassett *et al.*, 2008; Axmacher *et al.*, 2010) and may have been detected in the BOLD signal amplitude increases in the MTL post-psilocybin (Figure 3); (5) unconstrained/disinhibited/anarchic MTL activity is a principal characteristic of primary states and the occurrence of these activities is consistent with a system at criticality; (6) brain activity in primary consciousness is closer to criticality-proper than it is during normal waking consciousness (which may be slightly sub-critical rather than perfectly critical).

The DMN, Introspection and Metacognition

DMN resting-state functional connectivity correlates positively with ratings of internal awareness (Vanhaudenhuyse *et al.*, 2011), depressive rumination (Berman *et al.*, 2011) and trait neuroticism (Adelstein *et al.*, 2011). DMN connectivity increases during mental time-travel (Andrews-Hanna *et al.*, 2010; Martin *et al.*, 2011) and activity in the medial prefrontal node of the DMN is reliably elevated in depression (Farb *et al.*, 2011; Lemogne *et al.*, 2012). These findings strongly implicate the DMN in introspective thought and suggest that hyper activity and connectivity in the DMN is related to a certain style of concerted introspection.

To step back, one of the primary hypotheses being developed here is that metacognition, and in particular, the human capacity for self-reflection, is an advanced behavior that rests on self-organized activity in the DMN and between the DMN and the MTLs. Thus, if the DMN is hyper-active and connected in depression, does this imply that mild depression is an evolutionarily advanced state? The phenomenon of "depressive realism" has been recognized for several decades (Dykman *et al.*, 1989; Haaga and Beck, 1995) and sits comfortably with the idea that a primary function of the DMN is to support metacognition (Fleming *et al.*, 2010). The suggestion is that increased DMN activity and connectivity in mild-depression promotes concerted introspection and an especially diligent style of reality-testing. However, what may be gained in mild depression (i.e., accurate reality testing) may be offset by a reciprocal decrease in flexible or divergent thinking (and positive mood).

The proposal that increased DMN activity and connectivity is a key functional correlate of concerted introspection, such as is seen in depression, may seem inconsistent with the association between DMN activity and mind-wandering (Mason *et al.*, 2007) but this is a conceptual problem that can be easily resolved. The positive relationship between increased BOLD signal in the DMN and the frequency of mind-wandering during task-performance (Mason *et al.*, 2007) tells us nothing about the nature or *style* of the cognition in the off-task state, it simply tells us that the mind has drifted off-task. It is known however, that the strength of inverse coupling between activity in the DMN and TPNs is increased when task performance is more consistent (Kelly *et al.*, 2008), implying increased focus and a relative decrease in off-task attentional lapses. DMN-TPN inverse coupling is decreased in patients with attention deficit/hyperactivity disorder (ADHD) (Hoekzema *et al.*, 2013) and increased after administration of the attention-enhancers modafinil (Schmaal *et al.*, 2013) and nicotine (Cole *et al.*, 2010). Thus, it is too simplistic to regard increased BOLD signal in the DMN as a correlate of freely-wandering cognition, and decreased inverse coupling between the DMN and TPN is probably a more informative index of this. As will be discussed later, this point is reinforced by findings that inverse coupling between the DMN and TPNs is decreased under psilocybin, and DMN activity and connectivity is also decreased. This is important because unconstrained, explorative thinking is a hallmark of the psychedelic state (see **Figure 5**).

In the next section we cite direct evidence for increased entropy in brain networks in psychedelic state and use this to support a general principle: that the transition from normal waking consciousness to primary consciousness is marked by an increase in system entropy.

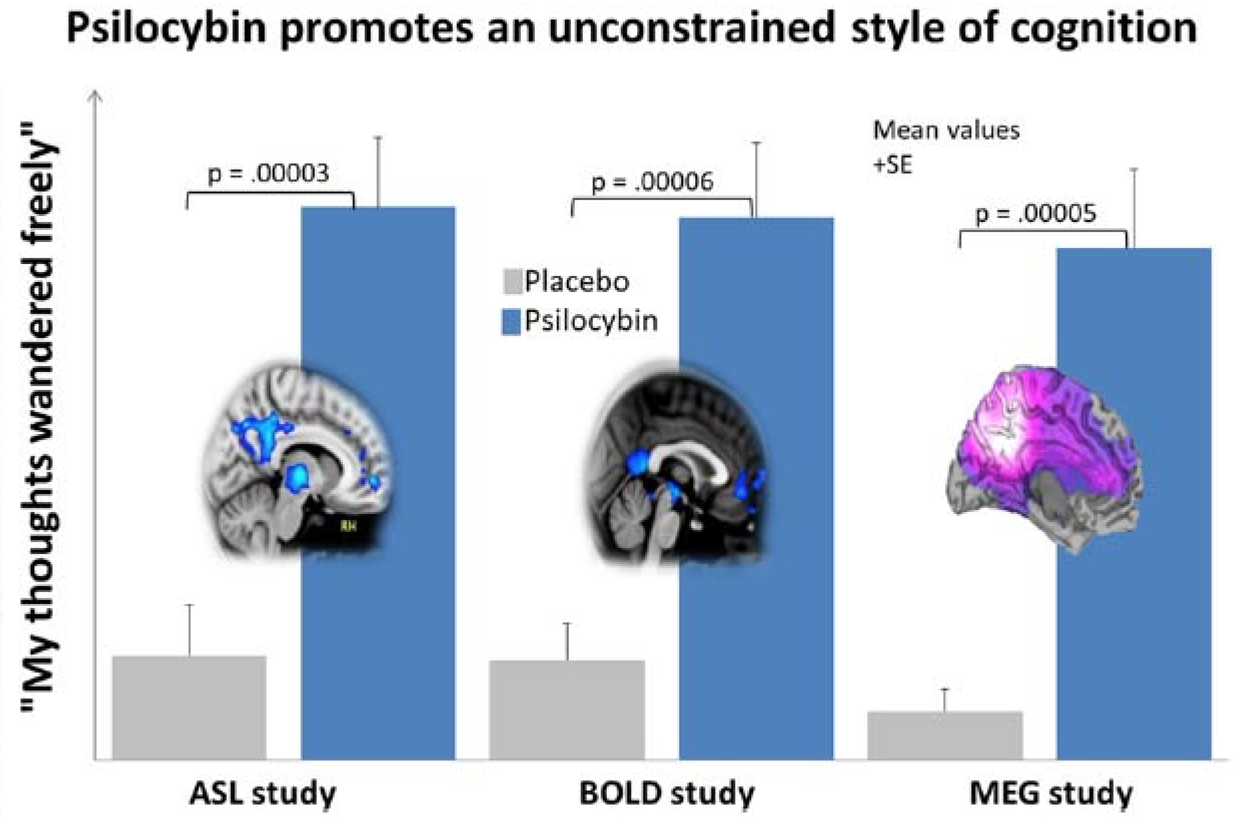

FIGURE 5 - Psilocybin promotes unconstrained thinking and decreases blood flow, venous oxygenation and oscillatory power in the DMN. This chart shows the average (+*SE*) ratings for the item "my thoughts wandered freely" in 3 neuroimaging studies, each involving the administration of psilocybin and placebo to 15 healthy volunteers. Ratings were given within 30 min of the end of the relevant resting state scans. This particular item was one of the highest rated items in all 3 studies and nicely communicates the quality of cognition that predominates in the psychedelic state. The brain image on the left displays the mean regional decreases in CBF post-psilocybin in the ASL study; the central image displays the mean regional decreases in BOLD signal post-psilocybin in the BOLD study; and the image on the right displays the mean regional decreases in alpha power post-psilocybin in the MEG study. All images were derived using a whole brain corrected threshold of $p < 0.05$.

Increased Network Entropy in the Psychedelic State

There is an emerging view in cognitive neuroscience that the brain self-organizes under normal conditions into transiently stable spatiotemporal configurations (Sporns *et al*., 2004; Shanahan, 2010; Deco and Corbetta, 2011; Tagliazucchi *et al*., 2012) and that this instability is maximal at a point where the global system is critically poised in a transition zone between order and chaos (Tononi *et al*., 1994; Shanahan, 2010; Deco and Jirsa, 2012; Tagliazucchi *et al*., 2012). In the present context, the "metastability" (Tognoli and Kelso, 2014) of a brain network is a measure of the variance in the network's intrinsic synchrony over time. That is, if the signal in all of the voxels within a given network deviates little from the network's mean signal, then variance is low, whereas if the signal in voxels fluctuate erratically, then variance is high. Thus, using the data from the BOLD fMRI study with psilocybin, we recently looked at changes in the variance of intra-network synchrony over time in nine canonical resting-state networks (Smith *et al*., 2009) pre and post placebo and psilocybin. Results revealed significantly increased network variance in high-level association networks after psilocybin but not in sensory specific and motor networks, and there were no changes after placebo. These results imply that activity in high-level networks becomes relatively disorganized under psilocybin, consistent with the entropic brain hypothesis.

To translate this result into a formal measure of entropy, we discretized the time course of intra-network synchrony over time into equal sized bins where each time-point could be entered into a bin depending on the variance in the network's synchrony at that time point. Doing this for each network, we built probability distributions of the variance of the intra-network synchrony across time from which we could then calculate the Shannon entropy for each network. Not surprisingly, increased entropy was observed in the networks in which there was increased variance post-psilocybin i.e., the high-level association networks (See **Figure 6**).

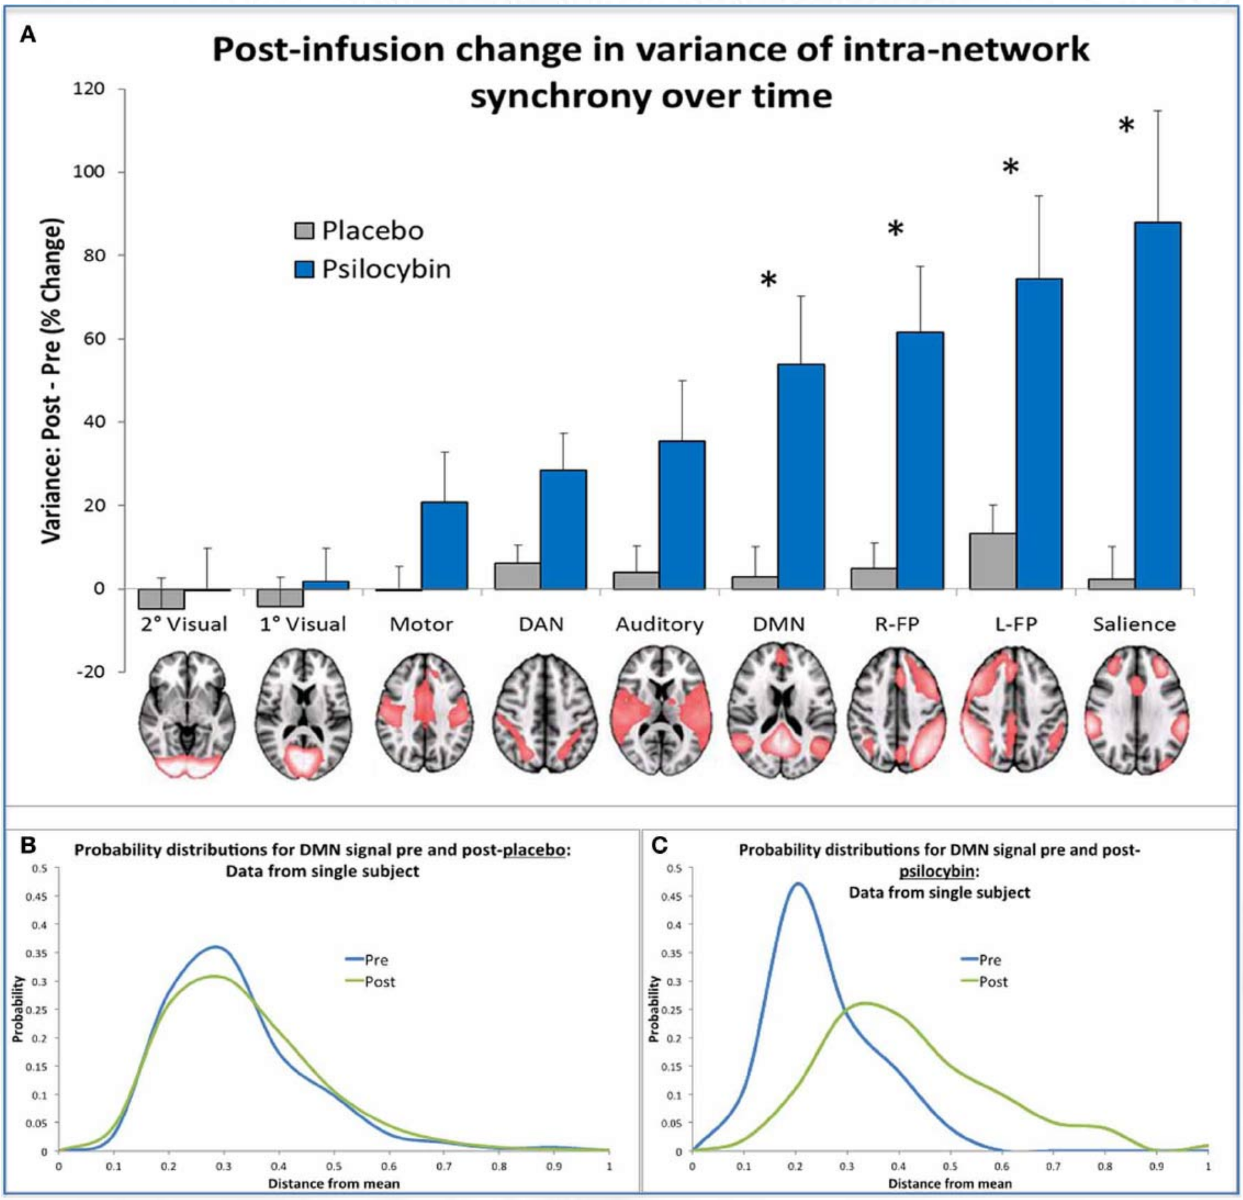

FIGURE 6 - **Changes in network metastability and entropy post-infusion of psilocybin. (A)** This chart displays the mean variance of the internal synchrony of 9 brain networks for the sample of 15 healthy volunteers, as a percentage change post vs. pre-infusion. A post-infusion increase in metastability for a specific network indicates that the mean signal in that network is a poor model of the activity in its constituent voxels, implying that the network is behaving more "chaotically" post-infusion than pre. Bonferonni correction gave a revised statistical threshold of $p < 0.006$ (0.05/9). One-sample (2-tailed) t-tests were performed, comparing the % change against zero. The significant networks are labeled with an asterisk. **(B,C)** These probability distributions were derived from data from the same single subject, by discretizing a measure of the internal synchrony of the DMN across time into bins. These bins reflect the distance a data point is from the mean and this gives a probability distribution of the variance of internal synchrony within a network for a given time period (e.g., a 5 min period of scanning). The probability distributions shown in **Chart B** were produced from placebo data where it is clear that prediction of internal network synchrony of the DMN across time is similar before and after infusion (i.e., the blue and green curves). The probability distributions shown in **Chart C** were derived using psilocybin data and here it is evident that following infusion of psilocybin (i.e., the green curve), prediction of internal network synchrony within the DMN is more difficult compared to pre infusion (the blue curve). When the entropy change was calculated for the group, significantly greater increases in entropy were found in the same networks highlighted in **(A)** (post-psilocybin vs. pre) vs. (post-placebo vs. pre).

To further assess entropy changes after psilocybin, we took a slightly different approach. Four regions were chosen from a limbic/paralimbic system based on prior knowledge that BOLD signal variance was increased in these regions under psilocybin. The regions included: the left and right hippocampi and the left and right anterior cingulate cortex (ACC). A threshold was set for connection strength such that only connections above a particular strength survived and were therefore said to "exist." This allowed functional connectivity motifs (connectivity graphs) to be identified at each time point in the time series. With 4 nodes, there were 64 possible connectivity motifs or graphs at any given time point. The results revealed a greater repertoire of motifs under psilocybin than either at baseline or after placebo. Indeed, a number of motifs were exclusive to the psilocybin condition. The entropy of a time series could then calculated by assessing the entropy of a sequence of motifs over a period of time (i.e., how easy/difficult is it to predict a sequence of motifs in a given state?). This is the same procedure one would follow in order to calculate the entropy of a transcribed passage of speech for example (i.e., the likelihood of certain words occurring in a coherent passage is not random, e.g., some words, such as "I," occur much more often than others). Thus, it was found that the sequence of motifs had significantly greater entropy under psilocybin than at baseline, meaning that a more random sequence of motifs played-out in the psychedelic state. This result implies that it is harder to predict the sequence of connectivity motifs in the psychedelic state because it is more random. This outcome is entirely consistent with the entropic brain hypothesis, which states that brain activity becomes more random and so harder to predict in primary states - of which the psychedelic state is an exemplar.

Criticality and Primary Consciousness

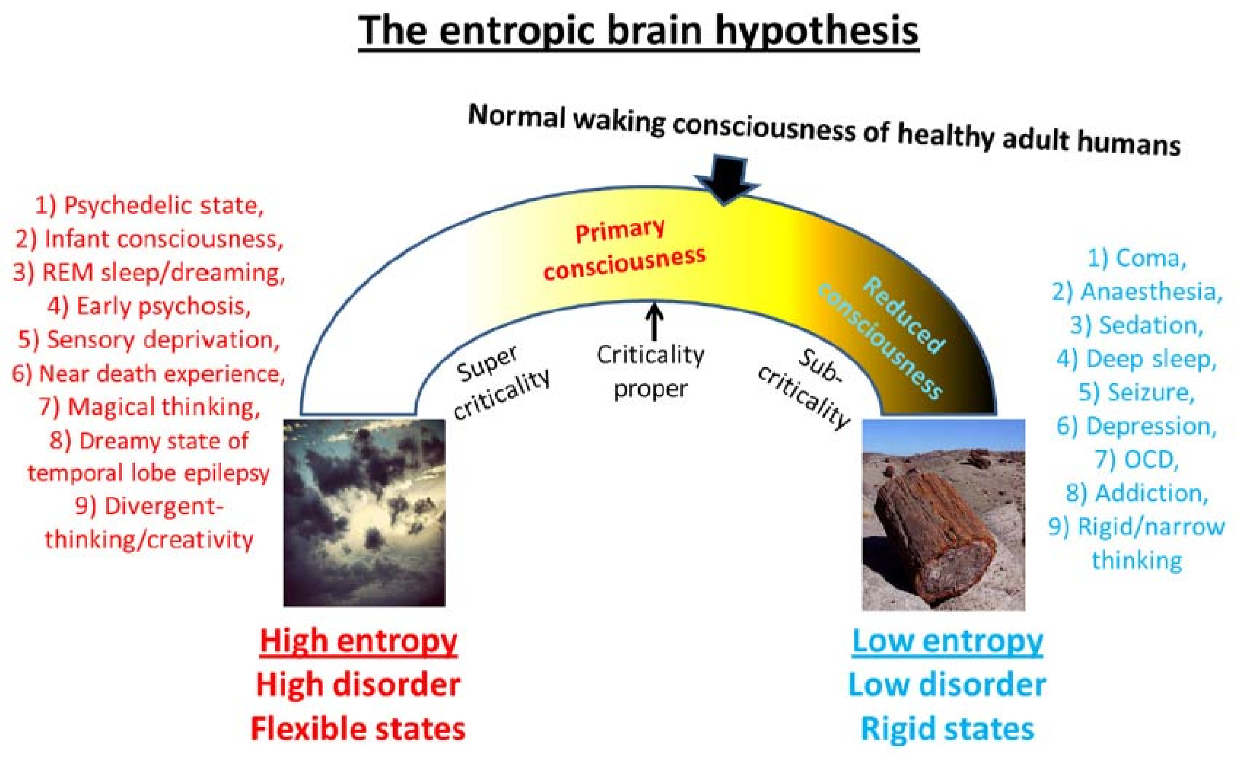
The DMN appears to have a consistently high level of activity, e.g., even when the DMN is relatively deactivated during goal-directed cognition, it is still receives more blood flow than elsewhere in the brain (Pfefferbaum *et al*., 2011). Thus, it can be inferred that one reason why the DMN is so highly and persistently active, is that it receive regular endogenous input from internal drivers. One such driver may be MTL activity (Laxton *et al*., 2010) and another may be input from brainstem nuclei such as the serotonergic raphe nuclei. Irrespective of what the specific drivers of the DMN are, its enduring presence fits comfortably with the idea that it is the seat of the ego (Carhart-Harris and Friston, 2010), as in healthy waking consciousness, one's sense of self is never far from consciousness:

> "Normally, there is nothing of which we are more certain than the feeling of our self, of our own ego." (Freud, 1930)

So how does the phenomenon of primary consciousness fit in here? The first thing to say is that primary consciousness may be a sub-optimal mode of cognition that has been superseded by a more reality-bound style of thinking, governed by the ego. However, if primary consciousness is a psychological atavism, and the psychedelic state is an exemplar of it, then how does this explain the putative utility of the psychedelic experience e.g., as an adjunct to psychotherapy (Moreno *et al*., 2006; Grob *et al*., 2011) and why do some people report being so profoundly affected by such experiences (and often seemingly for the better) (Griffiths *et al*., 2008; Carhart-Harris and Nutt, 2010; MacLean *et al*., 2011)?

The phenomenon of depression can help us here. Cognition during an episode of depression is characteristically inflexible; the patient's focus is almost entirely inward and self-critical, and *he/she is unable to remove him/herself from this state* (Holtzheimer and Mayberg, 2011). In the previous section, depressive realism was discussed in relation to hyper activity and connectivity within the DMN; however, in severe depression, cognition cannot be said to be optimal. Depressed patients typically perceive themselves and their world through an unyielding pessimism (Styron, 1992). Depressed patients' cognitive style may become too fixed, such that the patient loses the ability to think and behave in a flexible manner. Underlying this phenomenon may be a decrease in metastability, such that one particular state, e.g., the introspective default-mode, comes to dominate cognition. The aggressive self-critical focus that accompanies a loss or abandonment of object-cathexis in depression (i.e., interest in or focus on objects in the world, such as work and people) quite naturally leads to suicidal thoughts and acts (Carhart-Harris *et al*., 2008). In consideration of these things, narrow-mindedness is to pessimism what openness (MacLean *et al*., 2011) is to optimism and strategies that promote the latter may be effective treatments for depression (see MacLean *et al*., 2011).

This article proposes that primary consciousness rests on more metastable dynamics than secondary consciousness, i.e., brain sub-states are less stable in primary consciousness. Thus, by implication, a broader repertoire of transient states may be visited in primary consciousness because the system is closer to criticality-proper. Moreover, it is the ability of psychedelics to disrupt stereotyped patterns of thought and behavior by disintegrating the patterns of activity upon which they rest that accounts for their therapeutic potential. This principle implies that a brain at criticality may be a "happier" brain. The schematic below (**Figure 7**) illustrates differences between primary and secondary consciousness. The model describes cognition in adult modern humans as "near critical" but "sub-critical" - meaning that its dynamics are poised in a position between the two extremes of formlessness and Petrification where there is an optimal balance between order and flexibility. However, because of maturational settling, the brain in secondary consciousness gravitates toward "order" and thus, the dynamics in this state are more accurately, (slightly) sub-critical. Psychedelics may be therapeutic because they work to normalize pathologically subcritical styles of thought (such as is seen in depression, OCD or addiction/craving for example) thereby returning the brain to a more critical mode of operating. Indeed, if the principle holds that a critical brain is a happy brain, then it would follow that psychedelics could be used to enhance well-being and divergent thinking, even in already healthy individuals. One negative consequence of this however could be the neglect of accurate reality-testing.



The entropic brain hypothesis
Normal waking consciousness of healthy adult humans
1) Psychedelic state,
2) Infant consciousness,
3) REM sleep/dreaming,
4) Early psychosis,
5) Sensory deprivation,
6) Near death experience,
7) Magical thinking,
8) Dreamy state of temporal lobe epilepsy
9) Divergent-thinking/creativity
Primary consciousness
Reduced consciousness
Super criticality
Criticality proper
Sub-criticality
1) Coma,
2) Anaesthesia,
3) Sedation,
4) Deep sleep,
5) Seizure,
6) Depression,
7) OCD,
8) Addiction,
9) Rigid/narrow thinking
High entropy
High disorder
Flexible states
Low entropy
Low disorder
Rigid states

FIGURE 7 - **Spectrum of cognitive states.** This schematic is intended to summarize much of what this paper has tried to communicate. It shows an "inverted u" relationship between entropy and cognition such that too high a value implies high flexibility but high disorder, whereas too low a value implies ordered but inflexible cognition. It is proposed that normal waking consciousness inhabits a position that is close to criticality but slightly sub-critical and primary states move brain activity and associated cognition toward a state of increased system entropy i.e., brain activity becomes more random and cognition becomes more flexible. It is proposed that primary states may actually be closer to criticality proper than secondary consciousness/normal waking consciousness.

Recent work has indeed supported the notion that brain activity is slightly sub-critical in normal waking consciousness (Priesemann *et al.*, 2013). One reason why it may be advantageous for the brain to operate just below criticality is that by doing so, it can exert better control over the rest of the natural world - most of which *is* critical. This may take the form of suppressing endogenous processes within the brain or interacting with the environment in order to shape it and thereby control it. Indeed, if control is the objective, then it makes sense that the brain should be more ordered than that which it wishes to control.

The idea that the brain is closer to criticality in the psychedelic state than in normal waking consciousness (**Figure 7**) has some intuitive appeal as some of the signatures of criticality, such as maximum metastability, avalanche phenomena and hypersensitivity to perturbation are consistent with the phenomenology of the psychedelic state. For example, if we consider just one of these: hypersensitivity to perturbation, it is well known that individuals are hypersensitive to environmental perturbations in the psychedelic state, which is why such emphasis is placed on the importance of managing the environment in which the psychedelic experience unfolds (Johnson *et al.*, 2008). Indeed, one explanation for why some people celebrate and romanticize the psychedelic experience and even consider it "sacred" (Schultes, 1980; McKenna, 1992), is that, in terms of criticality, brain activity does actually become more consistent closer with the rest of nature in this state i.e., it moves closer to criticality-proper and so is more in harmony with the rest of nature.

A final speculation that is worth sharing, is that the claim that psychedelics work to lower repression and facilitate access to the psychoanalytic unconscious, may relate to the brain moving out of a sub-critical mode of functioning and into a critical one, enabling transient windows of segregation or modularity to occur (e.g., with "anarchic" MTL activity) because of the breakdown of the system's hierarchical structure. Indeed, repression may depend on the brain operating in a sub-critical mode, since this would constrain consciousness and limit its breadth. Phenomena such as spontaneous personal insights and the complex imagery that often plays out in psychedelic state (Cohen, 1967) and dreaming, may depend on a suspension of repression, enabling cascade-like processes to propagate through the brain [e.g., from the MTLs to the association cortices (Bartolomei *et al.*, 2012)]. Such processes may depend on a reduction of DMN control over MTL activity.

The Therapeutic Potential of Psychedelics

Many psychiatrists working with psychedelics in the 1950s and 60s expressed great enthusiasm about their therapeutic potential (Crocket *et al.*, 1963; Abramson, 1967; Grinspoon and Bakalar, 1979; Grof, 1980) but there was an unfortunate failure to substantiate these beliefs with properly controlled studies. Subsequent reviews and meta-analyses have suggested an impressive efficacy, especially in relation to the use of LSD in the treatment of alcohol dependence (Mangini, 1998; Dyck, 2005; Krebs and Johansen, 2012) and modern trials have lent some support to this sentiment (Moreno *et al.*, 2006; Grob *et al.*, 2011). For example, a single high dose of psilocybin produced profound existential experiences in healthy volunteers that had a lasting beneficial impact on subjective well-being (Griffiths *et al.*, 2006, 2008) and a moderate single dose of psilocybin administered to patients with advanced-stage cancer significantly reduced anxiety and depression scores for months after the acute experience (Grob *et al.*, 2011). In another study, symptoms of obsessive compulsive disorder (OCD) were significantly reduced after psilocybin (Moreno *et al.*, 2006). Supplementing these controlled studies, we surveyed over 500 recreational drug users, and found that 67% of LSD users and 60% of psilocybin users claimed that use of these drugs had produced long-term positive effects on their sense of well-being (Carhart-Harris and Nutt, 2010), consistent with the results of the aforementioned controlled studies (Griffiths *et al.*, 2006, 2011). To place this in a context, only 6% of alcohol users claimed such improvements from alcohol use (Carhart-Harris and Nutt, 2010). One of the most remarkable properties of psychedelics is their potential to have a lasting impact on personality and outlook (McGlothlin and Arnold, 1971; Studerus *et al.*, 2011). Personality traits are known to be relatively fixed by adulthood (Costa and McCrae, 1997; McCrae and Costa, 1997), however, the personality trait "openness" was found to be significantly increased over 14 months after a single controlled administration of psilocybin (MacLean *et al.*, 2011). Moreover, neuroimaging studies (Carhart-Harris *et al.*, 2012a) have found decreased activity and connectivity after psilocybin in brain regions (e.g., the mPFC) and networks (e.g., the DMN) that are over-engaged in depression (Greicius *et al.*, 2007; Berman *et al.*, 2011) but normalized by a range of effective treatments (Goldapple *et al.*, 2004; Mayberg *et al.*, 2005; Kennedy *et al.*, 2007; Deakin *et al.*, 2008).

Classic psychedelics are all agonists at the serotonin 2A receptor (Glennon *et al.*, 1984; Vollenweider *et al.*, 1998) and 5-HT$_{2A}$R antagonism blocks the positive mood effects of psilocybin (Kometer *et al.*, 2012) and MDMA (van Wel *et al.*, 2012). 5-HT$_{2A}$R expression is upregulated in depression (Bhagwagar *et al.*, 2006) likely because of low synaptic 5-HT (Cahir *et al.*, 2007). Positron emission tomography (PET) studies in humans found positive correlations between 5-HT$_{2A}$R binding and trait neuroticism (Frokjaer *et al.*, 2008) and pessimism (Meyer *et al.*, 2003). This may imply that 5-HT$_{2A}$R upregulation, due to low synaptic 5-HT, reflects a state of chronically deficient post-synaptic 5-HT$_{2A}$R stimulation that contributes to inflexible patterns of (negative) thought such as are seen in depression. 5-HT$_{2A}$R-stimulation may therefore work to reverse this, effectively "lubricating" cognition.

Given our knowledge of the biological effects psychedelics, a comprehensive model can be presented in which psychedelics: (1) stimulate the 5-HT$_{2A}$ receptor (Glennon *et al.*, 1984), (2) depolarize deep-layer pyramidal neurons (Andrade, 2011), (3) desynchronize cortical activity, (4) "disintegrate" brain networks (Carhart-Harris *et al.*, 2012a), (5) increase network metastability and (6) increase the repertoire of connectivity motifs within a limbic/paralimbic network. The net effect of these processes is an increase in system entropy (formally reflected in points 5 and 6) as the system enters criticality-proper.

Thus, in summary, it is hypothesized that there is a basic mechanism by which psychedelics can be helpful in psychiatry, whether they be used to treat depression, OCD (Moreno *et al.*, 2006) or addiction (Krebs and Johansen, 2012). Specifically, it is proposed that psychedelics work by dismantling reinforced patterns of negative thought and behavior by breaking down the stable spatiotemporal patterns of brain activity upon which they rest. An important caveat however, is that in order for this process to be beneficial, the drug-induced transitions to, and the return from primary consciousness, must be mediated by appropriate therapeutic care (Johnson *et al.*, 2008). Moving the brain out of sub-critical modes and into unfamiliar terrain may present some risks (e.g., loss of contact with reality and persistent magical/delusional thinking) if not properly managed (Johnson *et al.*, 2008).

The Spiritual Experience and Primary Consciousness

> "If we consider contemporary accounts of the mystical consciousness, we can see that the individuality, the "I," disappears and is in a sense "annihilated." (Stace, 1961)

In the psychology of religion, one of the most remarkable findings has been that it is possible, by way of a single high dose of psilocybin, to reliably induce profound spiritual experiences in healthy volunteers that are effectively indistinguishable from spontaneously-occurring spiritual experiences (Griffiths *et al.*, 2006). Perhaps this finding should not be so surprising, psilocybin containing mushrooms have been used for centuries in shamanic "healing" ceremonies (Hofmann, 1980), and in a famous study in the 1960s, high-dose psilocybin was administered to theology students partaking in a religious service on Good Friday and emphatic spiritual experiences were reported (Doblin, 1991). The so-called "entheogenic" (generating the divine) properties of psilocybin appear to be shared by the other classic psychedelics such as LSD and DMT but not the "psychedelic-like" compounds, MDMA and cannabis (Carhart-Harris and Nutt, 2010; Lyvers and Meester, 2012). It is intriguing that entheogenic properties appear to be specific to 5-HT$_{2A}$R agonist classic psychedelics and this suggests a key role for this receptor in their genesis.

In William James' famous lectures on the psychology of religion he proposed that spiritual experiences depend on the emergence of what he referred to as the "subconscious" or "subliminal" mind into consciousness (James, 1968). Referring to what psychoanalysis calls "the unconscious." James said: "*[T]his is obviously the larger part of each of us, for it is the abode of everything that is latent and the reservoir of everything that passes unrecorded or unobserved… It is the source of our dreams… In it arise whatever mystical experiences we may have… It is also the fountain-head of much that feeds our religion. In persons deep in the religious life - and this is my conclusion - the door into this region seems unusually wide open.*" (James, 1968).

James' ideas are consistent with those of Carl Jung; however, Jung extended them, arguing that the unconscious hosts the psychological remnants of our phylogenetic ancestry. In dreams, psychosis and other altered states, archetypal themes shaped by human history emerge into consciousness (Jung, 1982a). Jung's account of the "collective" unconscious fits comfortably with the phenomenology of the psychedelic experience. Archetypal themes feature heavily in user "trip reports" (Masters and Houston, 1966; Shanon, 2002), as they do in religious iconography. For Jung, religion is a manifestation of the collective unconscious, expressed in a symbolic and ritual form: "*The brain is inherited from its ancestors; it is the deposit of the psychic functioning of the whole human race. In the brain, the instincts are preformed, and so are the primordial images which have always been the basis of man's thinking - the whole treasure-house of mythological motifs… Religious symbols have a distinctly "revelatory" character; they are usually spontaneous products of unconscious psychic activity … they have developed, plant-like, as natural manifestations of the human psyche.*" (Jung, 1982b).

Jung's ideas offer an appealing explanation for the content of religious experiences, as well as the content of high-dose psychedelic experiences; however, a more systematic treatise on the spiritual experience was provided by Walter Stace in 1960 (Stace, 1961). Stace's work is particularly useful because his ideas resonate with the findings of recent neuroimaging studies relevant to the neurobiology of spiritual experiences. Based on a thorough review of first-person accounts derived from individuals from a variety of different faiths, Stace identified seven universal components of the spiritual experience: 1) diminished spatial and temporal awareness, 2) diminished subjectivity (equivalent to increased objectivity), 3) feelings of profound joy and peace, 4) a sense of divinity, 5) paradoxicality (where two opposing things appear to be true), 6) ineffability (the difficulty of expressing the experience in words) and 7) a sense of oneness with the world, otherwise known as "the unitive experience."

Importantly, in Stace's synopsis, he identified the unitive experience as the core characteristic of the spiritual experience. Freud referred to the same phenomenon as the "oceanic state" (Freud, 1930). Stace explained that in profound spiritual experiences the complex *multiplicity* of normal consciousness collapses into a simpler state where a sense of an all-encompassing unity or "oneness" with others, the world and/or "God" is felt. He emphasized that there is a collapse in the most fundamental dualities of consciousness (i.e., *self* vs. *other*, *subject* vs. *object* and *internal* vs. *external*) in the unitive state. Moreover, he also showed that reports of unitary consciousness are consistent throughout the different religions - emphasizing its universality and cultural independence (Stace, 1961).

Freud had some important things to say about the unitive state that are directly relevant to the entropic brain hypothesis. For example, when discussing his friend's description of an "oceanic feeling" when in religious practice, Freud says: "*Pathology has made us acquainted with a great number of states in which the boundary lines between the ego and the external world become uncertain... Further reflection tells us that the adult's ego-feeling cannot have been the same from the beginning. It must have gone through a process of development... (For example,) an infant at the breast does not as yet distinguish his ego from the external world; he gradually learns to do so. Our present ego-feeling is therefore only a shrunken residue of a much more inclusive - indeed, an all-embracing feeling, which (early in development] corresponded to a more intimate bond between the ego and the world. If we assume that there are many people in whose mental life this primary ego-feeling has persisted to a greater or less degree, it would exist in them side by side with the narrower and more sharply demarcated ego feeling of maturity, like a counterpart to it. In that case, the ideational contents appropriate to it would be precisely those of limitlessness and of a bond with the universe - the same ideas with which my friend elucidated the "oceanic feeling.*"" (Freud, 1930).

Thus, Stace and Freud's descriptions of the spiritual experience are entirely consistent with the view of the primary state as being regressive. Moreover, they are also consistent with view that the human brain developed through ontogeny and phylogeny to minimize disorder/uncertainty (Friston, 2010). In the schematic presented in **Figure 7**, primary consciousness is depicted as being more supercritical than normal waking consciousness. Indeed, at the extreme end of supercriticality is maximum entropy, which is equivalent to formlessness or complete disorder. Formerly, there is no difference between entropy in this thermodynamic sense (depicted as complete disorder) and entropy in the information theory sense, where there is maximum uncertainty about the system - because there is no order on which to base any predictions.

The System Mechanics of Primary States

Extending this, the mechanics underlying the onset of true primary states (for which the spiritual experiences is an example) can be viewed in relation to the second law of thermodynamics. Explicitly, in the absence of a regular driving input, the system (i.e., self-organized brain activity) will inevitably degrade or collapse toward formlessness or maximum entropy. The interesting question that follows therefore is: *what is the driving input that ceases in primary states*? This paper proposes that regular MTL activity is a crucial driver of the DMN. Although, interestingly, there is also evidence that the usual clock-like firing of serotonin neurons in the dorsal raphe nuclei completely ceases in both the psychedelic state (Aghajanian *et al*., 1968; Aghajanian and Vandermaelen, 1982) and REM sleep (Trulson and Jacobs, 1979) and there is some indirect evidence that the DMN may be (at least partially) a serotonergic system coupled to dorsal raphe activity (Zhou *et al*., 2010).

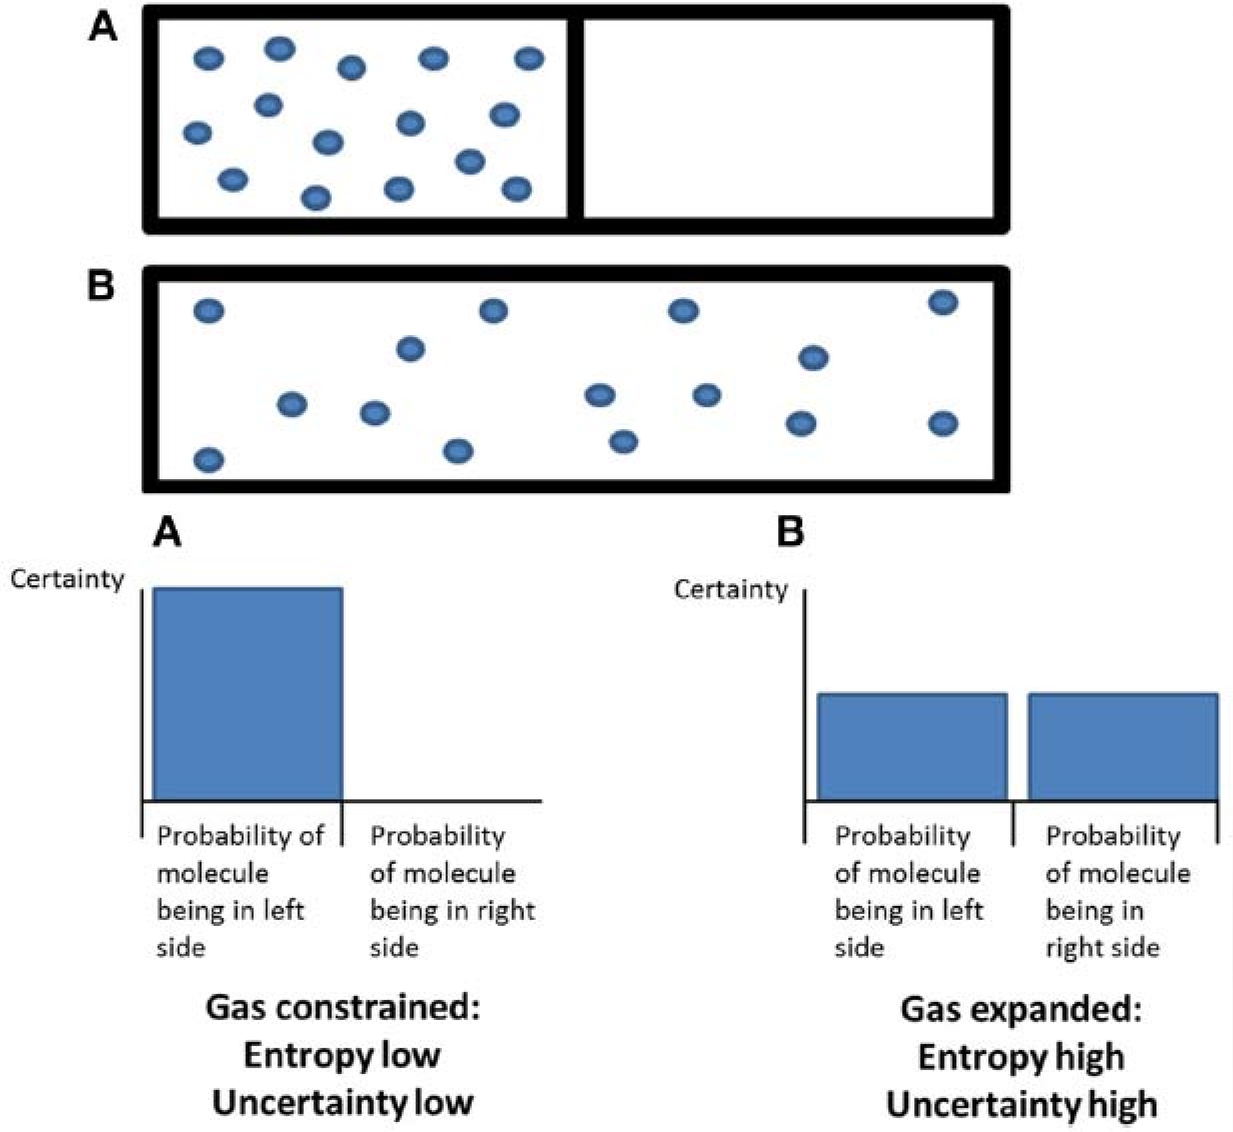
During secondary consciousness, the brain can enter a *multiplicity* of different states and microstates (Tononi, 2010) but due to "winner-takes all," or more strictly, "winnerless" (Rabinovich *et al*., 2001) competition between states ["winnerless" because critical instability or metastability dictates that a state's "victory" is transient (Friston *et al*., 2012b)] the global system only ever entertains *one* winning state at any one time (Baars, 2005). However, according to the entropic brain hypothesis, in primary states, the potential multiplicity of possible states is not obliterated but rather extended because the *selectivity* and *conspicuity* of a winning state is reduced, and so more transient states may be visited. In dynamical terms, this would be expressed as attractor basins or valleys (defining transient states) becoming shallower in primary states, i.e., the attractor landscape is flattened in primary states.

Conversely, in depression, OCD and addiction, specific states (e.g., the default-mode in depression) may be frequented more regularly than others - and this may be observed as certain mental states (e.g., introspection in depression or craving in addiction) or behaviors (e.g., compulsive acts in OCD) being habitually revisited in a stereotyped fashion. Moreover, these states may be relatively stable i.e., their basins of attraction are relatively steep since the patterns of activity upon which they rest have become entrenched. In such scenarios, uncertainty about the system is minimized because we know that it possesses a particular character. It is intriguing to consider therefore that disorders such as depression, OCD and addiction could be functional in some sense, perhaps working to resist a more catastrophic collapse to primary consciousness (with the onset of a psychotic episode for example) by reinforcing stable patterns of activity.

The following example may help to illustrate what is meant by competition between conscious states - and the loss of it in primary consciousness. Functional brain imaging has identified distinct brain networks that subserve distinct psychological functions. For example, the DMN is associated with introspective thought (Andrews-Hanna *et al*., 2010) and a dorsal frontoparietal attention network (DAN) is associated with visuospatial attention (Corbetta *et al*., 1998; Fox *et al*., 2006) and is a classic example of a "task positive network" (TPN) - i.e., a network of regions that are consistently activated during goal-directed cognition. If the brain was to be sampled during a primary state (such as a psychedelic state) we would predict that the rules that normally apply to normal waking consciousness will become less robust. Indeed, we recently found this to be so when analysing the degree of orthogonality or "anti-correlation" between the DMN and TPN post-psilocybin. Post-drug there was a significant reduction in the DMN-TPN anticorrelation, consistent with these networks becoming less different or more similar (i.e., a flattening of the attractor landscape). The same decrease in DMN-TPN anticorrelation has been found in experienced meditators during rest (Brewer *et al*., 2011) and meditation (Froeliger *et al*., 2012). Moreover, decreased DMN-TPN inverse coupling is especially marked during a particular style of meditation referred to as "non-dual awareness" (Josipovic *et al*., 2011). This is interesting because this style of meditation promotes the same collapse of dualities that was identified by Stace (and Freud) as constituting the core of the spiritual experience. The DMN is closely associated with self-reflection, subjectivity and introspection, and task positive networks are associated with the inverse of these things, i.e., focus-on and scrutiny of the external world (Raichle *et al*., 2001). Thus, it follows that DMN and TPN activity *must* be competitive or orthogonal in order to avoid confusion over what constitutes *self*, *subject* and *internal* on the one hand, and *other*, *object* and *external* on the other. It is important to highlight that disturbance in one's sense of self, and particularly one's sense of existing apart from one's environment, is a hallmark of the spiritual (Stace, 1961) and psychedelic experience (Carhart-Harris *et al*., 2012b). Moreover, as in the psychedelic state (Carhart-Harris *et al*., 2012a; Carhart-Harris *et al*., 2012b), a number of studies have found decreased DMN activity (Farb *et al*., 2007; Brewer *et al*., 2011; Hasenkamp *et al*., 2012) as well as decreased DMN-TPN inverse coupling in meditation (Brewer *et al*., 2011; Josipovic *et al*., 2011; Froeliger *et al*., 2012).

The contravention or corruption of important rules about brain organization may explain the sense of confusion and uncertainty that accompanies a transition from secondary to primary consciousness. In the information theoretical sense, "uncertainty" is a synonym for entropy (Friston, 2010; Ben-Naim, 2012) - and disorder and uncertainty are effectively equivalents. Entropy in information theory is reflected in the shape of a probability distribution (Ben-Naim, 2012), i.e., we have less confidence (or more uncertainty) about something when the distribution is broader or more evenly spread. This is because it is more difficult to predict what the outcome of an individual sampling trial would be because the system behaves relatively randomly (Ben-Naim, 2012). Conversely, a probability distribution with a sharp peak would reflect a well-ordered system or high-precision, confidence or assuredness (Friston, 2010). In the specific context of the DMN and the psychedelic state, just as there is increased variance in parameters defining the DMN (e.g., coupling between the nodes of the DMN or rhythmic alpha oscillations in the PCC), so there is uncertainty about ones sense of self - typically described as "ego-disintegration." Thus, according to the entropic brain hypothesis, just as normally robust principles about the brain lose definition in primary states, so confidence is lost in "how the world is" and "who one is" as a personality.

In addition to the word "uncertainty," other terms that have been used as synonyms for entropy include: "freedom," "disorder" and "expansion." The example of a gas expanding post release of constraints is often used as a metaphor to help explain what is meant by entropy increasing [e.g., in relation to the second law of thermodynamics (Ben-Naim, 2012)] See **Figure 8**. In the information theoretical sense, entropy/uncertainty increases as the gas expands because with greater expansion, it is more difficult to predict the spatial location of a single molecule. It is probably not coincidental that these physical principles resonate with popular descriptions of the psychedelic experience (Huxley, 1959; Bowers and Freedman, 1966; Masters and Houston, 1972; Grinspoon and Bakalar, 1981; Merkur, 1998). For example, the term "consciousness-expansion" is often used to describe the psychedelic experience - and this may be an inadvertent reference to increased system entropy in the psychedelic state.



A

A
Certainty
Probability of molecule being in left side
Probability of molecule being in right side
Gas constrained:
Entropy low
Uncertainty low
B
Certainty
Probability of molecule being in left side
Probability of molecule being in right side
Gas expanded:
Entropy high
Uncertainty high

FIGURE 8 - Gas expansion post-release of constraints as a metaphor for increased entropy in primary states. (A) Entropy is low while the gas is constrained. **(B)** Entropy increases once constraints are released. In an information theoretical sense, entropy/uncertainty is increased post-expansion because it is more difficult to predict the spatial location of a single molecule. In primary vs. secondary states, it is hypothesized that the biological parameters known to define key brain states (e.g., the default-mode) become more variant or less predictable, thus causing the subject to become less certain in themselves and their experience of the world.

Developing the Construct Validity of Primary Consciousness

To develop the construct validity of primary consciousness, it will be necessary to show that the identified parameters of primary consciousness have high *internal* and *convergent* validity (i.e., properties of primary consciousness must be shown to exist in a range of different primary states) and sufficient *discriminant* validity (i.e., these properties must be shown to be sufficiently *specific* to primary states, i.e., to be absent in non-primary states). To assist this undertaking, it will be important to optimize subjective rating scales designed for assessing primary consciousness. For example, first it will be necessary to identify key experiences that are considered characteristic of primary states (i.e., visual analog scale items such as "my imagination was extremely vivid" or "the experience had a dreamlike quality" that can be rated during or after a candidate primary state) and then it will be important to test whether different candidate primary states (e.g., dreaming, onset-phase psychosis, the near death experience, the sensory-deprived state and the psychedelic drug state) score highly on these items - and that candidate non-primary states (e.g., normal waking consciousness, the anaesthetized or sedated state, and the depressed state) do not. This will enable the convergent and discriminant validity of these measures to be tested and developed. Similarly, by identifying neurobiological characteristics hypothesized to be essential to primary states (e.g., decreased DMN-MTL coupling, disinhibited MTL activity, decreased DMN-TPN anti-correlation, decreased alpha power in the PCC and increased metastability in resting-state networks), it will be important to determine those that most *reliably* and *specifically* identify primary over non-primary states.

As discussed in The research value of psychedelics, psychedelic drugs are especially useful tools for studying primary states as they allow for primary consciousness to be "switched on" with a relatively high degree of experimental control (e.g., with intravenous infusion of a classic psychedelic). Hypotheses about the neurobiological character of primary states can therefore be effectively tested by psychedelic drugs. However, in order to test and develop the generalizability of these hypotheses, research with alternative primary states are required. For example, it would be interesting to carry out simultaneous fMRI-EEG or MEG work with a focus on REM sleep, or to study patients exhibiting early-phase psychotic symptoms with these techniques. Longitudinal analyses looking at brain maturation would also be relevant, where infant consciousness is hypothesized to be reflective of primary consciousness.

Developing the Construct Validity of Secondary Consciousness and the Ego

As outlined above, a key distinction between the primary and secondary modes of cognition is that secondary consciousness pays deference to reality and diligently seeks to represent the world as *precisely* as possible, whereas primary consciousness is less firmly anchored to reality and is easily misled by simple explanations motivated by wishes and fears. One way this distinction could be tested would be to utilize a measure of metacognitive accuracy (Fleming *et al*., 2010). As outlined above, metacognition, and specifically the ability to reflect upon one's own introspection, is a particularly advanced behavior associated with the DMN (Fleming *et al*., 2010). For example, a behavioral paradigm could be designed that requires a participant's friend to rate the participant's personality, e.g., using a standard personality inventory. Then, during scanning, the participant could be asked to predict their friend's ratings - and crucially, to provide an additional confidence rating for their own predictions. This could be done under a psychedelic drug and under placebo in a within-subjects design with 2 different friends for each condition, counterbalanced for key factors (e.g., familiarity, intimacy, fondness, duration of relationship etc). This task would provide a behavioral index of a high-level metacognitive function associated with the ego (theory-of-mind). The hypothesis would be that participants would be *less confident* in their predictions of their friend's ratings post-psilocybin and that the accuracy of their predictions would also be compromised. Biologically, one would hypothesize decreased within-DMN coupling during the prediction process and a reduction in induced alpha-oscillations in the PCC.

Conclusions

This article has argued that scientific research with psychedelic drugs can have a revitalizing effect on psychoanalysis and an informing influence on mainstream psychology and psychiatry. Rather than discuss the content and interpretation of psychoanalytically-relevant material, we have adopted a mechanistic approach, in keeping with the mainstream cognitive neuroscience. This article proposes that a distinction can be made between two fundamentally different modes of cognition: primary and secondary consciousness. Primary consciousness is associated with unconstrained cognition and less ordered (higher-entropy) neurodynamics, whereas secondary consciousness is associated with constrained cognition and more ordered neurodynamics (i.e., that strikes an evolutionarily advantageous balance between order and disorder - that may or more not be perfectly "critical"). It is hoped that this mechanistic model will help catalyze a synthesis between psychoanalytic theory and cognitive neuroscience that can be mutually beneficial to both disciplines.

It is a fair criticism of this paper that it has given insufficient consideration to the phenomenological content of the relevant altered states of consciousness, and to the specifics of Freudian theory, and so by neglecting this, has failed to present a sufficiently compelling case that these states have anything to do with psychoanalytic theory. To some extent, this charge can be conceded; however, as outlined in the introduction, the intention of this paper was to develop a mechanistic account of altered states of consciousness based on the quantity of entropy, and this task has demanded a substantial amount of space. A more thorough discussion of the phenomenology of primary states is required to develop the case that they show characteristics that are consistent with Freudian accounts of "the unconscious" or "Id." The reader should be made aware however, that this has been attempted before (Carhart-Harris, 2007; Carhart-Harris and Friston, 2010).

To conclude, it is perhaps not surprising that with only dreaming and psychosis at its disposal, psychoanalysis has failed to convince the scientific community that the psychoanalytic unconscious exists (Hassin *et al.*, 2005). From a neuroscientific perspective, dreaming and psychosis are notoriously difficult to study. The occurrence of dreaming in sleep impedes experimental control and psychosis is an especially complex and variegated phenomenon. However, for those brave enough to embrace it, research with psychedelics could herald the beginning of a new scientifically informed-psychoanalysis that has the potential to influence modern psychology and psychiatry. The unique scientific value of psychedelics rests in their capacity to make consciously accessible that which is latent in the mind. This paper takes the position that mainstream psychology and psychiatry have underappreciated the depth of the human mind by neglecting schools of thought that posit the existence an unconscious mind. Indeed, psychedelics' greatest value may be as a remedy for ignorance of the unconscious mind.

> "He who would fathom the psyche must not confuse it with consciousness, else he veils from his own sight the object he wishes to explore." (Jung, 1961)
>
> "Man's worst sin is unconsciousness." (Jung, 1969)

Acknowledgments

We would like to thank the reviewers for their useful comments on previous versions of this manuscript. Robin L. Carhart-Harris would also like to acknowledge that Robert Leech coined the term "the entropic brain" when in conversation with him over the topic of his and David Nutt's psilocybin fMRI results. Robin L. Carhart-Harris is currently supported by the Medical Research Council.

Conflict of Interest Statement: The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Notes

1. Entropy in its purest information theoretical sense is a dimensionless quantity that is used for measuring uncertainty or ignorance about the state of a system. By implication, entropy/uncertainty is greater the more random a system is. Thus, entropy is most strictly a measure of uncertainty but it also reflects the degree of randomness or disorder in a system (Ben-Naim, 2012).
2. The free energy principle is an extension of predictive coding (Dayan *et al.*, 1995) and tries to explain how biological systems, such as the brain, maintain their order by developing inferences and behaviors that serve to minimize surprise and uncertainty. Free-energy is formally related to entropy in the information theoretical sense, where entropy (uncertainty) is the average of free-energy (surprise) (Friston, 2010). See also (Friston *et al.*, 2012a) for a philosophical discussion of free-energy.
3. Self-organized criticality (SOC) is a property of certain systems that gravitate toward a 'critical' point in a transition zone between order and disorder. Critical systems display certain characteristics such as power-law scaling (Bak *et al.*, 1987). SOC is typically observed in slowly driven non-equilibrium systems, with many units that interact in a non-linear fashion (Bak *et al.*, 1987; Jensen, 1998).
4. The ego can be defined as a sensation of possessing an integrated and immutable identity, i.e., "this is me" or "I am like this." It is equivalent therefore with one's sense of self. In psychoanalytical theory however, the ego is also a system which works in concert with and against other processes in the brain to determine the quality of consciousness. It is worth noting that Freud's term for the ego was 'the I' and it was only in the standard translation from German that the term "the ego" became associated with Freud (1927). In everyday (lay) usage, "ego" has become synonymous with exaggerated self-confidence or an inflated ego/sense of self.
5. A fully-developed, adult ego or sense of self.
6. A network of functionally and structurally connected brain regions that show high spontaneous or "on-

going" metabolism yet a relative deactivation during goal-directed cognition (Raichle *et al.*, 2001).

7. Functional connectivity is defined as temporal correlations between spatially distinct neurophysiological events (Karl Friston). Resting-state refers to task-free, unconstrained experimental conditions (typically sitting or lying still with eyes closed).
8. The quality of returning to an earlier state of development.
9. A regressive, pre-ego style of consciousness characterized by unconstrained brain dynamics and cognition. The psychedelic state is an exemplar of primary consciousness and REM sleep and early psychosis are others.
10. A cognitive capacity unique to adult humans and dependent on the formation of a mature ego. Metacognition means "cognition about cognition." Examples include: self-reflection, theory-of-mind and mental time-travel. (Fleming *et al.*, 2012).
11. The term "infancy" is used here in an extended sense to mean the period from birth to two years of age.
12. The earliest humans, i.e., archaic homo-sapiens.
13. The style of consciousness of healthy, adult, modern humans during waking. Secondary consciousness is "constrained" relative to primary consciousness, both in a mechanistic and qualitative sense
14. A style of cognition in which causal relationships between phenomena are assumed despite an absence of supportive scientific evidence. Examples include superstition, and metaphysical beliefs. Crucially, such beliefs usually honor an emotional sentiment such as a wish (or fear) that something is true.

Abstract

The entropic brain hypothesis proposes that within upper and lower limits, after which consciousness may be lost, the entropy of spontaneous brain activity indexes the informational richness of conscious states. Here the hypothesis is revisited four years on from its original publication. It is shown that the principle that the entropy of brain activity is elevated in the psychedelic state is increasingly well supported by separate and independent studies and analyses, and evidence for greater brain criticality under psychedelics is also highlighted. It is argued that heightened brain criticality enables the brain to be more sensitive to intrinsic and extrinsic perturbations which may translate as a heightened susceptibility to "set" and "setting". This updated version of the original entropic brain hypothesis now offers more concrete information on specific measures of brain entropy and suggests new studies to scrutinise it further, as well as examine its utility for describing and informing the treatment of psychiatric and neurological conditions such as depression and disorders of consciousness.

Keywords: Psychedelics, Serotonin, Criticality, 5-HT$_{2A}$, Depression, Entropy.

1. Introduction

This review aims to revisit and update a previous theory of conscious states, namely the 'entropic brain' hypothesis (Carhart-Harris *et al.*, 2014). The entropic brain proposes that the 'qualia' or subjective quality of any given conscious state, and specifically the 'richness' of its content, can be indexed by a quantitative measure of the magnitude of entropy (in the information theoretic sense) in a given parameter of spontaneous brain activity, such as oscillations in electrical potentials recorded with EEG or MEG. The hypothesis was, and is, heavily influenced by basic principles of information theory and more specifically, the notion that entropy indexes simultaneously both our uncertainty about the future behaviour of a dynamic system and its information content - such that greater entropy equals greater uncertainty and information-content. Thus, the entropic brain maintains that uncertainty and information-content are near equivalents and that entropic-brain-states are experienced as content-rich but unpredictable and uncertain. The theory lends heavily from research with 'classic' psychedelic[1] compounds, which have been shown to robustly and reliably increase brain entropy within the 'psychedelic state'.

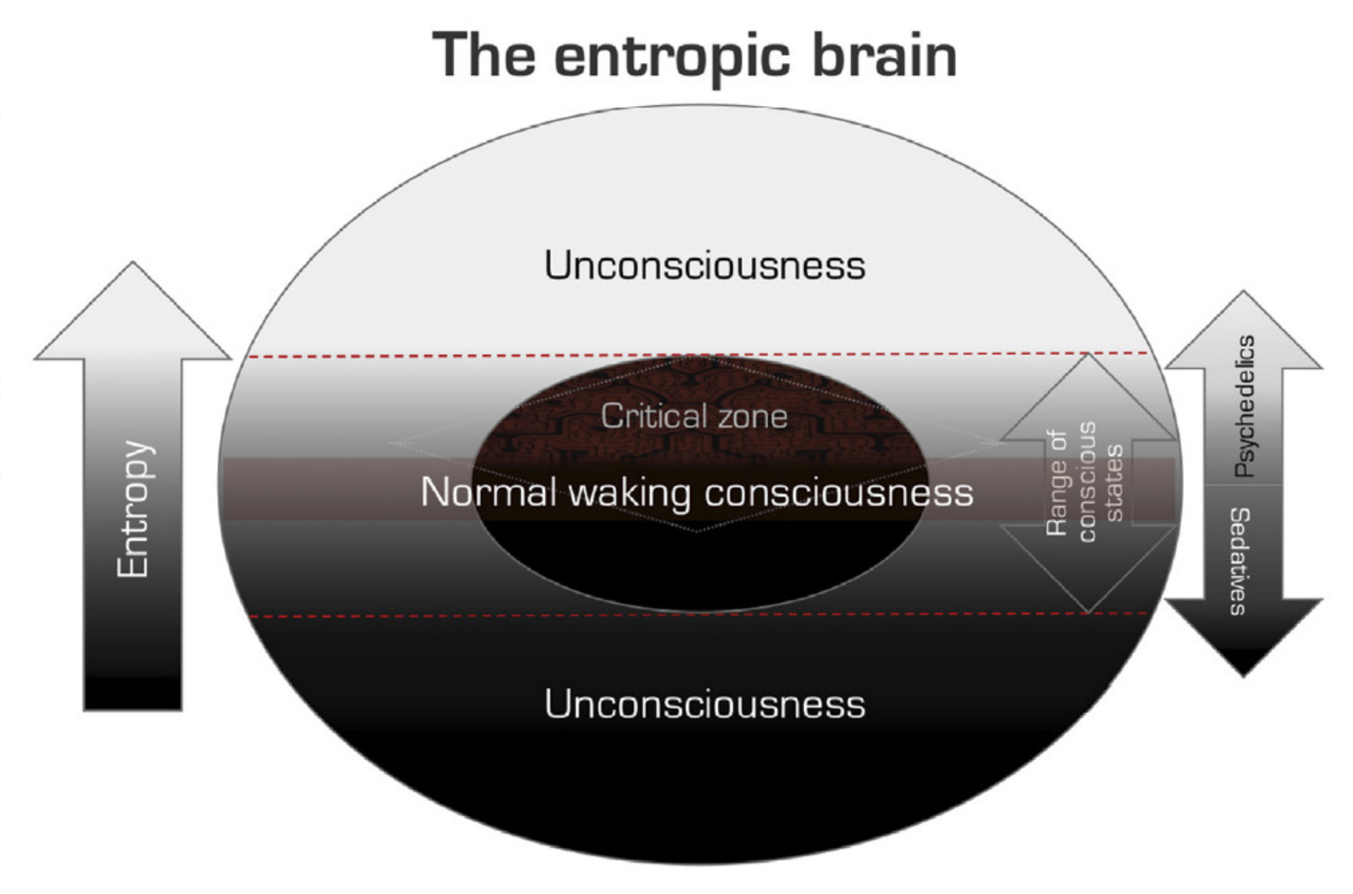

Fig. 1. The entropic brain. Consciousness is proposed to arise within a critical zone at which the entropy or complexity of brain activity is neither too ordered nor disordered. Normal waking consciousness is proposed to inhabit a band within this zone, albeit towards its upper end. Psychedelic compounds are proposed to shift brain entropy and conscious content upwards, higher within the zone of criticality, towards greater conscious content, flexibility of mind and emotional lability but with a trade-off on the preservation of assumptions or beliefs and the sense of familiarity and assuredness they confer. Brain entropy (and criticality) may reach an upper limit at which consciousness is effectively lost - perhaps because phenomenal experience cannot be preserved beyond this point and thus, remembered. Sedatives and anaesthetics shift the brain downwards, i.e. into a subcritical zone and eventual unconsciousness, through loss of content and phenomenal experience. N.B. This figure is intended to be a working schematic; no hard claims are made about the relative scale or dimensions of each domain.

The great merit of applying the measure of entropy in cognitive neuroscience is that it is uniquely adept at bridging the physical and subjective divide; mere flip sides of the same coin - but different sides nonetheless.[2] Since publication of the initial entropic brain paper in 2014 (Carhart-Harris *et al.*, 2014), a number of new functional brain imaging studies with psychedelics have been published (Alonso *et al.*, 2015; Atasoy *et al.*, 2017; Barrett *et al.*, 2017; Bouso *et al.*, 2015; Carhart-Harris *et al.*, 2016b, 2017c; Kaelen *et al.*, 2016; Kraehenmann *et al.*, 2015, 2016; Lebedev *et al.*, 2015, 2016; Mueller *et al.*, 2017; Muller *et al.*, 2017; Palhano-Fontes *et al.*, 2015; Petri *et al.*, 2014; Preller *et al.*, 2016, 2017; Roseman *et al.*, 2014, 2016, 2017; Sampedro *et al.*, 2017; Sanches *et al.*, 2016; Schartner *et al.*, 2017; Schenberg *et al.*, 2015; Schmidt *et al.*, 2017; Speth *et al.*, 2016; Tagliazucchi *et al.*, 2014, 2016b; Timmermann *et al.*, 2017; Valle *et al.*, 2016a; Viol *et al.*, 2017). These, plus time, reflection, and the publication of new imaging studies on other altered states e.g. (Schartner *et al.*, 2015) plus new research on serotonin function (e.g. (Matias *et al.*, 2017), have motivated the present revision.

Key components of this revision include: 1) a more explicit statement that the qualia of time-averaged conscious states can be predicted by brain entropy, 2) reference to specific measures of entropy thought to meaningfully index the qualia of conscious states, 3) a specific example of an important empirical, therapeutically relevant question that may be tackled by the hypothesis, 4) a specific example of a clinical problem (namely disorders of consciousness) where the hypothesis may inspire a novel intervention, 5) new data and thoughts on properties of brain criticality in the psychedelic state, 6) how heightened brain criticality confers maximal sensitivity to perturbation via intrinsic or extrinsic sources ("set" and "setting), 7) how there may be an upper bound to the entropic brain principle beyond which unconsciousness occurs (Fig. 1), and 8) how recent findings on brain serotonin encoding behavioural responses to uncertainty mesh well with the entropic brain hypothesis.

2. An update on neuroimaging studies with psychedelics

According to a PubMed search at the time of submission (January 2018), since the 2014 publication of the original entropic brain paper, there have been over 30 new empirical neuroimaging papers published on the effects of psychedelics on the human brain. Since there are relatively few human neuroimaging teams working with these compounds, it is relatively easy to locate where these have come from, namely: Spain (Alonso *et al.*, 2015; Bouso *et al.*, 2015; McKenna and Riba, 2017; Sanches *et al.*, 2016; Valle *et al.*, 2016b), Switzerland (Barrett *et al.*, 2017; Kraehenmann *et al.*, 2015, 2016; Mueller *et al.*, 2017; Muller *et al.*, 2017; Preller *et al.*, 2016, 2017; Schmidt *et al.*, 2017), Brazil (Palhano-Fontes *et al.*, 2015; Schenberg *et al.*, 2015; Viol *et al.*, 2017), and the UK (Atasoy *et al.*, 2017; Carhart-Harris *et al.*, 2016b, 2017c; Kaelen *et al.*, 2016; Lebedev *et al.*, 2015, 2016; Petri *et al.*, 2014; Roseman *et al.*, 2014, 2016, 2017; Schartner *et al.*, 2017; Speth *et al.*, 2016; Tagliazucchi *et al.*, 2016b; Timmermann *et al.*, 2017). One aspect of the present task is to digest these recent contributions and summarise what they have added to our understanding of the human brain effects of psychedelics. Given the focus of the present paper, this will be done with specific reference to the entropic brain hypothesis.

The first thing to note is that the theory has received significant empirical support since its introduction in 2014 (Atasoy *et al.*, 2017; Lebedev *et al.*, 2016; Schartner *et al.*, 2017; Tagliazucchi *et al.*, 2014; Viol *et al.*, 2017). For example, analyses of Lempel-Ziv complexity or entropy (in the extended sense) in MEG-measured spontaneous brain activity under a range of psychedelic (i.e. LSD and psilocybin) and psychedelic-like (i.e. ketamine) drugs revealed consistently increased brain entropy in the psychedelic state (Schartner *et al.*, 2017). Moreover, the magnitude of these increases in entropy correlated with the subjective intensity of the drug 'trips' (Schartner *et al.*, 2017). It was also found that fMRI-measured brain entropy was elevated acutely under LSD and that the magnitude of this, predicted subsequent changes in personality two weeks later (Lebedev *et al.*, 2016). In terms of outside replication, a separate team recently reported increased fMRI-measured brain entropy under a psychedelic, in this case, with the DMT-containing drink, ayahuasca (Viol *et al.*, 2017); moreover, an especially recent study by my group recorded increased brain entropy under intravenous DMT, using EEG and the Lempel-Ziv measure (Timmermann *et al.*, 2018).

[1] Classic psychedelics are perhaps best defined pharmacologically as drugs that have direct agonist properties at the serotonin 2A receptor subtype (Nichols, 2016). Classic examples include the major tryptamines: LSD, psilocybin and dimethyltryptamine

[2] The philosophical position that mind and brain are two aspects of or 'ways to look at' the same phenomenon, like two sides of the same coin, is known as 'dual-aspect theory' or 'dual-aspect monism'. The position of *the entropic brain* is that 'mind' is fundamentally 'information' but the informational 'code' is physically and dynamically instantiated in brain activity and can therefore be decoded. Ubiquitous contingencies may be key to how, at least theoretically, we may 'decode' brain to mind - but a difference in *aspect* will always exist, no matter how successful the decoding, as this difference is fundamental.

Another notable recent contribution relates to the novel application of connectome harmonics to the psychedelic state (Atasoy *et al.*, 2017). Consistent with the entropic brain hypothesis (Carhart-Harris *et al.*, 2014), as well as previous analyses with fMRI and psilocybin (Tagliazucchi *et al.*, 2014), this approach revealed an expanded repertoire of brain states under LSD, and again, this effect correlated with the intensity of the subjective experience (Atasoy *et al*., 2017). To our knowledge, this is the first time that a property of brain criticality under a psychedelic has been clearly and intentionally measured (here the power law distribution of connectome-harmonic brain states) and the results were intriguing, with an apparent enhancement of criticality under LSD relative to the normal waking state (Atasoy *et al*., 2017). As with findings of increased brain entropy under psychedelics (e.g. Schartner *et al*., 2017), increased brain criticality relative to normal waking consciousness (or indeed any other state of consciousness) is an anomaly in the scientific literature (Atasoy *et al*., 2017), and may therefore speak to the exceptionalness of the psychedelic state, something that is widely recognised by those who have experienced their remarkable subjective effects (Huxley, 1959) - but not so much by the broader cognitive neuroscience community. It would be encouraging to think that these novel neurobiological findings may pique the interest of mainstream 'psychedelic-experience-naive' cognitive neuroscientists in the same way that the remarkable psychological effects and clinical potential of psychedelics have piqued the interest of philosophers (Milliere, 2017; Letheby, 2016), psychologists (Watts *et al*., 2017) and psychiatrists (Carhart-Harris and Goodwin, 2017), regardless of firsthand experience.

3. The functional meaning of 'increased brain entropy'?

The first thing to note is that there is strong evidence that the entropy of spontaneous brain activity is reduced during states of reduced consciousness (Olofsen *et al*., 2008; Schartner *et al*., 2015; Zhang *et al*., 2001; Burioka *et al*., 2005) and that entropy measures can be used to accurately distinguish between waking consciousness, loss of consciousness and even the minimally conscious state (Casali *et al*., 2013; Schartner *et al*., 2015; Zhang *et al*., 2001). In this context, the discovery of a state in which brain entropy is elevated above its already high level at normal waking consciousness is truly noteworthy (Schartner *et al*., 2017). If entropy indexes the 'level of consciousness', does it not follow that higher entropy in the psychedelic state relates to an increase in some quality of consciousness above its (already high) level during the normal awake state? It is important not to romanticise the psychedelic experience here, with mystical-sounding notions of 'expanded-consciousness', but equally, one should not be shy of the result nor its functional implications. Accordingly, it seems entirely reasonable to infer that there is an expansion in some key property of consciousness under psychedelics, while another may be compromised, e.g. analytical and convergent thinking (Carter *et al*., 2005; Kuypers *et al*., 2016).

It is proposed here that, to a critical point, beyond which the ability to preserve phenomenal experience and thus consciously reflect on it may be entirely lost, the property of consciousness that is most reliably indexed by brain entropy and enhanced under psychedelics is its *richness*. Other terms that could refer to the same property might be: 'content', 'complexity' and 'information'. These largely interchangeable terms harmonise well with the nomenclature of the measures themselves. Indeed, this easy mapping between the measures' names and the subjective feeling states they invoke, was, and remains, an inspiration behind the original *entropic brain* idea. It is maintained that this mapping is robust against charges of category conflation as there is actually little extrapolation being done; even in the strictest mathematical sense, *entropy is uncertainty* (Ben-Naim, 2007). The interpretation of entropy as 'information' (in its familiar sense) may depend, in part, on the process of decoding, i.e. that a decoder be able to 'make sense' of the potentially rich information content of a complex, unpredictable phenomenon (Gleick, 2011). As with 'uncertainty', reference to entropy as 'information' (Shannon, 1949), has led to charges of anthropomorphism (Gleick, 2011). In this context, a key challenge for the entropic brain hypothesis is to decipher the complex code instantiated by brain activity in order to may make more specific and compelling mappings to the feeling states they encode.

4. How might we better test the entropic brain theory?

4.1. Specific challenges

Improving our mappings between spontaneous brain and mind phenomena is a major scientific challenge. Doing so will enable us to better characterise and predict properties of different conscious states, and where appropriate, treat psychiatric and neurological disorders. Since it is the spontaneous brain activity underlying conscious states about which we are most interested, our techniques for realising this mapping will benefit most from retaining an intimacy to the original phenomena of interest. By implication, the study of stimulus-evoked transients, including discrete perturbations - such as brain stimulation (Casali *et al*., 2013; Massimini *et al*., 2009) or responses within specific behavioural paradigms, may have relatively limited explanatory potential due to their being detached from the central phenomena of interest, i.e. spontaneous 'states' - naturally unfolding across time. In contrast, improving our methods of sampling spontaneous mind and brain states in situ may yield more relevant insights.

Studying spontaneous processes comes with major challenges however; for example, in contrast to carefully controlled manipulations, experimental control is ceded when we choose to sample spontaneous phenomena in their natural form. A related challenge, perhaps best known in the context of physics, is that in sampling phenomena, we may cause an unintended perturbation and thus confound what inferences can be made on the phenomenon of interest. This is known as 'the observer effect' and more strictly, 'the uncertainty principle', and it is not an easy problem to resolve.

> "*Nature is sensitive to our experiments.*" (Gleick, 2011)

Moreover, in the context of psychedelic research, it has proved apparent that instructing participants to engage in certain behaviours or with certain stimuli tends to suppress the intensity of the basal, 'ongoing' psychedelic state. Another issue is that interpretations of results based on controlled experimental perturbations should carry important caveats - and these are not always stated. More specifically, likely due to a generalised inability to engage with stimuli that are relatively unengaging and/or difficult to focus on when in the throes of an intrinsically stimulating psychedelic 'trip', it is typical for such experiments to yield (arguably uninteresting) negative findings - e.g. see (Muthukumaraswamy *et al*., 2013; Timmermann *et al*., 2017) for relevant discussions. Similar critiques have been made of findings of impaired cognition and brain responsiveness in pathological conditions such as schizophrenia and/or major depressive disorder - since the most plausible (but less exciting) interpretation of such negative findings is that the patient is simply less able and/or willing to engage with tasks and stimuli in question, and thus, the impairment(s) are generalised rather than specific. Caution is therefore advised when choosing to employ conventional behavioural paradigms in the context of acute administration studies with psychedelics, as this may encourage specific inferences to be made on what are in actuality, non-specific negative outcomes.

4.2. Proposed solutions

In the mid 1990s cognitive neuroscientist Francisco Varela conceded that no simple 'theoretical fix' or 'missing ingredient' could magically bridge the ontological divide between brain/ objective and mind/subjective phenomena (Varela, 1996). In conceding this simple but essential point, he was then able to promote a pragmatic approach to the problem. He proposed that it is still very much possible to make meaningful mappings between irreducible 'mind-stuff' and intimately associated 'brain-stuff' - such that translations between them become relatively seamless, and differences, unobvious. In making this point, Varela cited Edmund Husserl's notion of 'fundamental correlation' and he named his approach 'neurophenomenology' (Varela, 1996).

The pragmatism of *neurophenomenology* chimes well with that of *the entropic brain*. However, it is recognised that significant improvements must be made in our sampling of both brain and mind, if more compelling and specific *fundamental correlations* are to be discovered. Moving beyond the supportive findings that have already been cited (Atasoy *et al*., 2017; Lebedev *et al*., 2016; Schartner *et al*., 2017; Tagliazucchi *et al*., 2014;Viol *et al*., 2017), a significant advancement for the entropic brain will be to go beyond the general but important statement that entropy is a (perhaps uniquely) powerful mind-brain bridge, to highlight specific cases where it bridges in a way that other measures do not. To help with this, it is encouraging to note that significant progress is being made in functional neuroimaging to develop more dynamically sensitive measures, such as sliding windows (Nakai *et al*., 2006), point-process (Tagliazucchi *et al*., 2012) and intrinsic ignition (Deco *et al*., 2017; Deco and Kringelbach, 2017) analyses; and with regards to subjective measures, experience sampling (Christoff *et al*., 2009) and so-called 'microphenomenology' (Petitmengin, 2017) hold much promise, particularly if combined with the aforementioned dynamic brain measures.

5. Do psychedelics facilitate emotional insight, and if so, how?

In the interests of encouraging the testing of the entropic brain hypothesis, it may be especially constructive to offer a specific example here of a particular problem felt to be deserving of special attention and about which a potential solution may be proposed.

Thankfully, the true origin and meaning of neologism 'psychedelic' is becoming increasingly well recognised and understood. It dates back to the mid 1950s and an exchange between two Brits (one, the famous author - Aldous Huxley) in which they sought to find a more appropriate term for these compounds (Huxley *et al.*, 1977). The objective was to devise a word that would better capture their core psychological properties than the relatively shallow and arguably misleading alternative 'hallucinogen'. It was Huxley's interlocuter, the psychiatrist and psychedelic research pioneer Humphrey Osmond who would coin the term 'psychedelic' - combining two ancient Greek words for 'mind' or 'soul' (*psyche*, *ψυχή*) and 'to reveal' or make manifest' or 'visible' (delein, δηλειν) - to lay principal emphasis on these compounds' *mind-revealing* effects.

The notion that a principal property of psychedelics is their ability to reveal aspects of the mind that are normally not fully visible, was (Cohen, 1964; Grof, 1979; Sandison, 1954), and remains (Carhart-Harris and Friston, 2010; Kraehenmann *et al.*, 2017a,b; Richards, 2015), widely accepted among those most familiar with their effects, if through direct personal experience, or second or third-hand observation. Remarkably however, that psychedelics do this, remains a mere assumption/hypothesis that has never been systematically measured and tested, and therefore given an opportunity to be verified or falsified.

It seems reasonable to begin by acknowledging that this relatively major oversight may be explainable - if not excusable - by the unreasonable difficulty of conducting human research with psychedelics[3] (Nutt *et al.*, 2013), let alone testing such an abstract and paradigm-challenging idea.[4] Tackling this problem pragmatically however, we may begin by deconstructing it into simpler, more concrete and testable components. One such component is that psychedelics facilitate 'emotional insight', i.e. definable as the acquisition of new thoughts, ideas or realisations about one's self (or 'persona' - to use a Jungian term), assumptions and behaviour. Such insights may (or may not) then lead to subsequent *changes* in assumptions, perspectives and behaviour. We may operationally define emotional insight using a revised version of a scale previously devised and employed to test the notion that dreams facilitate emotional insight (Edwards *et al.*, 2013).[5] This measure could be employed within a placebo-controlled study with a psychedelic, with the hypothesis that scores would be significantly higher in relation to the psychedelic experience than with placebo. Moreover, to add specificity and thus, potential strength to subsequent inferences, a psychoactive control drug could be introduced, such as a benzodiazepine, stimulant or non-psychedelic dissociative. Interestingly, a recent study largely adhered to such a design and found greater reported psychological insight in relation to the psychedelic (psilocybin) experience than with experiences produced by an active control (dextromethorphan) (Carbonaro *et al.*, 2017)

If further positive findings were to be obtained, key questions would then ensue, such as: what underlies such emotional insight (e.g. in terms of brain activity), and are such events amenable to capture and measurement in real-time, i.e. as they arise, as opposed to merely in retrospect? If the insight arises as a discrete event or epoch in time, then it stands to reason that it is amenable to capture, but if it is protracted, even to the extent that it crystallises after the psychedelic 'trip' has ended, then capturing and measuring this seems less feasible. In the interests of pragmatism (and plausibility), let us imagine that the entropic beginnings of emotional insight, do occur in discernable epochs under psychedelics. If we accept this possibility, how then might we capture such epochs and assess their relationship to insight?

[3] The reasons for this are manifold but can perhaps most simply and accurately be traced to stigma and related conservatism affecting key decision makers within governments, funding bodies, ethics boards, mainstream scientific communities and senior institutional figureheads. From experience, psychedelic research is an endeavor the establishment is far readier to say "no" to than "yes".

[4] Paradigm-challenging because expressed in psychoanalytic or psychodynamic terms, it is the principle that the unconscious mind exists and its existence can be tested.

[5] To assist other researchers, a revised, albeit as yet unvalidated emotional insight scale is provided as a supplementary file attached to this paper. This scale is currently in the process of validation - but others are invited to contribute to this process.

Button-press to signify the occurrence of discrete spontaneous events is an approach that has been used in the past, e.g. in relation to auditory hallucinations in psychosis (Leroy *et al.*, 2017) and spontaneously arising thoughts (Ellamil *et al.*,2016) but the overhanging psychological influence of the instruction to button press, as well as the subsequent motor actions, associated artefacts and the preceding deliberation on and intention to act, may suppress and/or confound the target phenomenon and therefore create false and/or unreliable attributions. Thus, an alternative to button press may be needed and one such example may be 'experience sampling', i.e. the procedure of cueing participants to report on the content of their recent conscious experience at random or pseudo-random time intervals (Christoff *et al.*, 2009). Such reports may be brief and constrained, e.g. delivered in the form of simple ratings, or more open, e.g. delivered through free speech. Due to the importance of brevity and desire not to interfere with the naturally unfolding experience, simple ratings may be the most practical option, particularly if concomitant functional neuroimaging recordings are being made - which are time sensitive and expensive (e.g. especially with fMRI). Thus, a simple brief rating of 'strength of emotion' and/or 'richness of conscious experience' could be used which could be supplemented post-hoc by detailed microphenomenology interviews (Petitmengin, 2017) that seek to evoke the original feeling and probe its nature with strategic questioning.

Importantly, we might improve on this entire approach by twinning the psychedelic experience with conditions known to be especially amenable to emotional arousal and insight. As already touched upon, this is especially pertinent in the context of neuroimaging, and particularly fMRI, where due to expense, as well as mechanical and comfort-related issues, individual scans typically last for approximately 5-15 min, and complete scanning sessions cover a period of approximately 60 min. Thus, introducing conditions in which emotional arousal and insight can be more easily coaxed, would serve a valuable function.

This could be done efficiently with music, structured in such a way that one may predict a priori, where intense experience and related insight may be most likely to occur. Experience sampling could track emotional strength/richness of experience in real-time and cues to rate/report on this could be sufficiently interspersed in time, so as to minimise interfering with the natural experience itself while being sufficiently regular to capture the desired events (e.g. a simple rating every 90-150 s). Although unconventional, if using fMRI for example, one might dedicate an entire scanning session of e.g. approximately 45 min to so-called resting-state scanning with music playing throughout. Inherently varying qualities within the music, such as individual 'songs' or periods within them, may serve as temporal flags to direct post-hoc reporting, which could be complemented by microphenomenology techniques (Petitmengin, 2017). If the spatially confined and auditorily loud nature of fMRI is considered unconducive to immersion in the experience and associated emotional release, then MEG or high density EEG might be more effective modalities.

A critical reader may ask, why such concern for the subjective measures, especially in a paper concerned primarily with a theory on brain function? The simple response to this is that questions of how experience is sampled should be given equivalent weight to questions of how concomitant brain activity is recorded, as the aim is to optimize the strength of our correlations between the two (Petitmengin, 2017). By implication, improving the fidelity of our subjective measures will serve this agenda as effectively as utilising the most powerful neuroimaging technologies and analyses.

How might we tie-in the entropic brain theory to this hypothetical study and its outcomes, and what predictions would we make about the magnitude of brain entropy during periods of intensified experience in which subsequent insight is reported? The clue may be in how the question has been framed, i.e. that there is a temporal sequence to events - with an increase in brain entropy coinciding with a period of intense immersion and 'information download' (which also feels unpredictable, openly explorative and experientially 'rich') followed by a subsequent period of normalisation of or reduction in brain entropy, that relates to a process of 'integrating', 'decoding' or sorting this information - and its subsequent crystallisation as 'insight'. Mechanisms and measures of *self-organisation* may be relevant in this context (Bak, 1997).

In partial support of these ideas, we have previously found that acute entropy under a psychedelic predicts sub-acute and potentially long-term changes in personality (i.e. increases in the personality trait 'openness' to experience) (Lebedev *et al.*, 2016), and certain qualities of brain activity (i.e. functional connectivity) have been found to change in an opposite direction after a psychedelic experience than during it (Carhart-Harris *et al.*, 2017c). These mechanisms might be likened to those discussed in relation to the creative process (Lubart, 2001), in which an experience of insight is preceded by planning (intention), free-association-like 'brainstorming' and a subsequent, delayed process of evaluation or verification (integration). Loosely, these mechanisms might also be related to the phenomena of divergent versus convergent thinking (Guilford, 1967; Kuypers *et al*., 2016) as well as exploratory versus exploitative search (Cohen *et al*., 2007), in which there is an initial entropic state that is exploratory and divergent in nature which is then followed by more protracted processes of cognitive convergence and 'exploitation'.

Before concluding this section, it is worth considering a couple of additional novel analytical approaches, i.e. in addition to applying information theoretic measures of entropy to brain data, it may be possible to measure the entropy of subjective experience itself, e.g. through the richness of the language used to describe it and in properties such as the rarity of the adjectives and phrases used and contingencies between words, phrases and categories or themes. Efforts are currently being made to explore how this can be done in a useful and meaningful way - but serving as inspiration are the impressive developments in natural speech analytics that have been made in psychiatry and psychopharmacology in recent years (Bedi *et al*., 2014, 2015). Relatedly, one may also apply validated measures of cognitive bizarreness to accounts of the psychedelic experience, as has been done recently (Kraehenmann *et al*., 2017).

Both brain and free-speech data might also be combined with machine learning methodologies with the aim of predicting new datasets and outcomes (e.g. see Carrillo *et al*., 2018) - however, by implication, entropic brain and mind states will be harder to predict, and perhaps also to derive predictions from; thus, the unreliability of machine learning algorithms to predict entropic brain states may be a specific hypothesis of the entropic brain theory itself - and this effect could be visually displayed via 'noisier' brain-to-mind visual reproductions (Naselaris *et al*., 2009).

6. Can psychedelic-induced consciousness-enrichment be used to treat disorders of consciousness?

Beyond what has just been discussed, let us consider another specific example of an area in which the entropic brain theory may be effectively applied. Brain entropy or 'complexity' has been found to reliably index conscious level in healthy people during normal waking consciousness versus the anaesthetised state, as well as in disorders of consciousness (Casali *et al*., 2013; Olofsen *et al*., 2008; Schartner *et al*., 2015; Zhang *et al*., 2001). Perhaps the most impressive research in this regard has been performed by Casali *et al*. (2013) who used transcranial magnetic stimulation (TMS) to perturb the brain in healthy individuals and patients with disorders of consciousness of varying degrees of severity. The Lempel-Ziv measure was then applied to EEG recordings of TMS-pulsed brain activity to yield the so-called perturbational-complexity index or PCI; for detailed explanations of Lempel-Ziv measures of brain activity, see (Schartner *et al*., 2015; Zhang *et al*., 2001). This PCI approach was remarkably reliable at differentiating between disorders of consciousness, e.g. with vegetative state patients scoring lowest, followed by patients in the minimal conscious state, the emerging from minimally conscious state and finally, locked-in syndrome and healthy controls during normal wakefulness (Casali *et al*., 2013). An even more recent study showed that the same Lempel-Ziv measure applied to spontaneous (i.e. restingstate, non-TMS perturbed) brain activity effectively differentiated between consciousness and unconsciousness in healthy individuals (Schartner *et al*., 2015), and in a separate earlier study, the same basic measure was found to index depth of anaesthesia with an almost 100% sensitivity and specificity (Zhang *et al*., 2001).

To our knowledge, until recently, it was generally thought that normal waking consciousness represents the (conscious) state of maximal brain entropy, since all comparison states characterised by a relative loss of consciousness, such as sleep, the anaesthetised and sedated states and disorders of consciousness, feature a corresponding reduction in brain entropy (Burioka *et al*., 2005; Schartner *et al*., 2015). It was a remarkable discovery therefore that the psychedelic state bucks this trend, with robust increases in brain entropy exceeding the levels associated with normal waking consciousness observed with different psychedelic compounds (Schartner *et al*., 2017).

In addition to questions about what we are to make about these findings, are questions about what we are to do with them? Interventions for disorders of consciousness are relatively ineffective and/or unreliable and range from the pharmacological to surgical (Giacino *et al*., 2014). If reductions in consciousness relate to reductions in brain entropy (Schartner *et al.*, 2015), and psychedelics robustly and reliably increase brain entropy (Schartner *et al.*, 2017), then does it not follow that psychedelics may be used to elevate conscious content in patients with disorders of consciousness?

Pragmatics and need, rather than cynical conservatism, should dictate how we proceed with this idea. One logical place to start might be with non-human animal research where the hypothesis that psychedelics lift entropy and thus, conscious content, from a sedated baseline may be tested. However, since it is difficult to assess conscious content in non-human animals, and anaesthesia to assist with recordings can confound interpretations, a logical advance on this would be to test whether psychedelics can lift both conscious content and entropy from a sedated baseline in humans. We might also extend this line of enquiry to sleep, with the hypothesis that psychedelics lift entropy and conscious content in NREM sleep, perhaps by switching the sleeper into dreamful REM sleep. Support for the REM-promoting effects of acutely administered psychedelics can be found in literature from the 1960s (Muzio *et al.*, 1966; Torda, 1968) and recent work has leant support to the association between the phenomenology of the psychedelic state and the dream state (Kraehenmann *et al.*, 2017; Tagliazucchi and Sanz, 2018) - see also (Carhart-Harris, 2007; Carhart-Harris and Nutt, 2014).

If these proof-of-principle experiments were to yield positive results, we might then consider taking the intervention to patients with disorders of consciousness. The normal procedure for informed consent in such patients would apply, and given the positive safety profile of psychedelics, and association with positive mental health outcomes (Carhart-Harris and Goodwin, 2017), albeit with important caveats related to context of use (Carhart-Harris *et al.*, 2018), a logical and ethical case could be made in favour of conducting such a study. Again, if positive results were to be found, considerations may then turn to how the intervention could be given in a more manageable way, e.g. via adherence to a 'microdosing' protocol (Fadiman, 2017), where threshold perceptible doses of psychedelics are given 2-3 times per week to (putatively) modulate improvements in mood and cognition. Moreover, where there is sufficient residual consciousness for this to be appropriate, such a dosing regimen might also be combined with conventional rehabilitation therapy.

7. Criticality

It was an original hypothesis of the initial entropic brain paper (Carhart-Harris *et al.*, 2014) that psychedelics tune the brain even closer to criticality[6] than is evident in normal waking consciousness and importantly, recent findings with fMRI and LSD do seem to support this idea (Atasoy *et al.*, 2017). That the brain exhibits characteristics of criticality is now well established (Hahn *et al.*, 2012; Fregnac, 2017; Tagliazucchi, 2017; Tagliazucchi *et al.*, 2016a), and there is some evidence to suggest that the brain ordinarily resides towards the sub-critical end of a general 'zone of criticality' (Priesemann *et al.*, 2014), i.e. brain criticality may be better thought of as 'zone' than a discrete critical 'point' (Moretti and Munoz, 2013) and the waking brain seems to be positioned closer to 'extreme order' or sub-criticality within this zone than 'extreme disorder' or super-criticality (Atasoy *et al.*, 2017; Priesemann *et al.*, 2013, 2014). Brain dynamics have been shown to shift towards sub-criticality with increasing cognitive load (Fagerholm *et al.*, 2015) and into super-criticality in epileptic seizure (Meisel *et al.*, 2012). As with entropy, cases of enhanced criticality above the already high level associated with the normal waking brain are relatively unheard of in the scientific literature; thus, by implication, increased criticality under psychedelics is exceptional (Atasoy *et al.*, 2017).

What then are we to make of this? Criticality is known to confer functional advantages to a system in terms of maximising the capacity and efficiency of information processing through optimizing adaptability while preserving order (Shew and Plenz, 2013), and it stands to reason that a system moving closer to criticality and/or shifting closer to the super-critical end of a critical zone is likely to favour flexibility and susceptibility to perturbation over preservation - as well as exploration over exploitation (Cohen *et al.*, 2007). Reflecting on some of the recent findings with psychedelics, this principle makes sense: for example, psychologically supported treatment with psychedelics has been associated with impressive improvements in psychiatric conditions such as addictions (Bogenschutz and Johnson, 2016), obsessive-compulsive disorder (Moreno *et al.*, 2006), and depression (Carhart-Harris *et al.*, 2016a, 2017a; Sanches *et al.*, 2016). Moreover, several of these conditions have been associated with brain sub-criticality (Carhart-Harris *et al.*, 2014) - particularly depression (Pezard *et al.*, 1996; Thomasson and Pezard, 1999; Thomasson *et al.*, 2000, 2002; Zhang *et al.*, 2001; Akdemir Akar *et al.*, 2015) - although contradictory evidence (e.g. Méndez *et al.*, 2012 ; Akdemir Akar *et al.*, 2015) suggests that the relationship between entropy and depression maybe be subtype and state specific (e.g. see

Akdemir Akar *et al*., 2015 and Zhang *et al*., 2001), as well as sensitive to medication status (Méndez *et al*., 2012).

Regarding the dynamics of mood itself, it is intriguing to entertain the thought that, within certain bounds, the super-critical end of the zone of criticality may favour positive mood - and perhaps even be a fundamental property of it (Carhart-Harris and Nutt, 2017; Thomasson *et al*., 2000, 2002), although there may be a tipping point, where the hyper-flexible (instable) individual may become vulnerable to a mania-related condition exhibiting behaviours such as agitation, inappropriate elation and grandiosity. It is noteworthy that such symptoms can sometimes be seen acutely and even sub-acutely with psychedelics (e.g. see https://erowid.org/experiences/), perhaps most commonly when the experience has been poorly integrated (Carhart-Harris *et al*., 2017b). The notion of 'spiritual bypassing' may be relevant here, in which transpersonal and/or 'spiritual' notions and ideals are (unconsciously) used to distract ourselves from and thus avoid directly working on painful personal material and/or developmental needs (Masters, 2010).

One of the signature properties of a critical system is a maximal sensitivity to perturbation (Bak, 1997; Hesse and Gross, 2014; Tagliazucchi *et al*., 2016a). By this token, we may ask whether and how this translates to the psychedelic experience? The importance of 'set' and 'setting' to the quality of a psychedelic trip has long been raised (Leary *et al*., 1963, and see also Hartogsohn, 2016) and a recent perspective piece on the assumed importance of context, both to the quality of the acute psychedelic experience and subsequent long-term psychological outcomes, has recently been published (Carhart-Harris *et al*., 2018). Intriguingly, as discussed above, it seems that not all stimuli have added impact in the psychedelic state - but are dependent on being sufficiently captivating and immersive for the individual (Kaelen *et al*., 2018). For example, in a recent clinical trial of psilocybin for depression, music played to patients during the treatment session that was well liked and in resonance with their underlying emotional state was found to be strongly associated with the occurrence of so-called 'peak experience' and positive therapeutic outcomes; however, if the music was out-of-synch with the patient's tastes and or emotional state, then positive clinical outcomes were diminished (Kaelen *et al*., 2018) - see also (Roseman *et al*., 2018).

There have been a small number of recent (Frecska *et al*., 2012; Kuypers *et al*., 2016) and historical reports (Harman *et al*., 1966; Janiger and Derios, 1989; McGlothlin *et al*., 1967) on enhancements in creative thinking in relation to psychedelics. However, this effect appears to be reserved for the divergent, explorative component of the creative process rather than the convergent aspect (Kuypers *et al*., 2016), which may depend more on critical thinking - and which may be impaired (at least acutely) under psychedelics (Carter *et al*., 2005; Kuypers *et al*., 2016). Bold claims have been made about the potential of so-called psychedelic 'microdosing' to enhance cognition (Waldmana, 2017; Fadiman, 2017) but as yet, there has been no published scientific verifications of this. If evidence was to accrue however, attunement of brain dynamics closer to criticality and an associated flexibility of thought could be considered a candidate mechanism - see (Carhart-Harris and Nutt, 2017) for relevant discussions. We should also be mindful of some of the conceptual dangers of super-criticality raised above however, namely (hypo)mania and so-called 'spiritual bypassing'.

Lastly, it is worth reflecting whether enhanced criticality under psychedelics (Atasoy *et al*., 2017) may express in other functionally useful ways. As touched on earlier, the ability of psychedelics to relax prior assumptions may provide the necessary preconditions for the emergence of spontaneous insight. Conceptually, it seems reasonable to suppose that attunement of brain activity towards criticality may be a mechanism underlying spontaneous insight under psychedelics (Atasoy *et al*., 2017). Avalanche-phenomena and/or cascading processes in responses to intrinsic perturbation are signatures of critical systems (Petermann *et al*., 2009) and may be involved in the disinhibition and associated 'release' of previously inhibited information under psychedelics (Alonso *et al*., 2015; Carhart-Harris *et al*., 2014; Kaelen *et al*., 2016). The collapse of functional hierarchies that serve to maintain the status quo may also be key, enabling freer communication between the different levels - such as between the evolutionarily older emotional circuitry of the brain (e.g. the limbic system) and the cortex, perhaps through periodic cascades propogating through the system (e.g. see Kaelen *et al*., 2016). These matters are speculative but deserving of discussion - if only to earmark them for the future when it is easier to formulate our hypotheses more clearly and test them accordingly.

> "The unconscious is a thing of nature." (Carl Jung)
>
> "In all chaos there is cosmos, in all disorder, a secret order." (Carl Jung)

8. Serotonin and the entropic brain

Before concluding this paper, it seems appropriate to link in recent advances in serotonin research to the entropic brain hypothesis. A particularly exciting development is the discovery that unlike the dopamine system (Schultz, 2016), serotonin appears not to encode classic reward/punishment information but rather value-nonspecific 'surprise' (Matias *et al.*, 2017). More specifically, optogenetic techniques in mice have revealed that serotonin expressing neurons within the dorsal raphe nuclei fire in response to unexpected outcomes independent of their value sign (Matias *et al.*, 2017). This matter is particularly intriguing as averaged surprise is formally equivalent to uncertainty, and is therefore effectively synonymous with entropy (Bestmann *et al.*, 2008). Key questions then ensue, why does this happen, and what function does it serve?[7]

One possible interpretation is that serotonin works to relax prior assumptions so as to weaken perseverative/habitual responding (Carhart-Harris and Nutt, 2017; Matias *et al.*, 2017). This relaxation of prior assumptions may be done to facilitate new learning, in conditions where prior assumptions become counterproductive and/or when the agent's environmental conditions are so volatile and changeable that heightened flexibility and exploration become the optimal strategies (Carhart-Harris and Nutt, 2017). Related ideas were recently discussed in a major review paper on brain serotonin function, where the significant pro-plasticity effects of serotonin were ascribed to increased signalling at the excitatory serotonin 2A receptor subtype (Carhart-Harris and Nutt, 2017). Indeed, signalling at other serotonin receptors (e.g. the postsynaptic serotonin 1A receptor subtype) may similarly encode behavioural responses to uncertainty, albeit in a different way, e.g. through enhancing one's endurance of uncertainty through stress-moderation, rather than adaption to it through changes in outlook and behaviour (Carhart-Harris and Nutt, 2017). Mechanistically, serotonin 2A receptor signalling has been hypothesised to serve a function analogous to 'annealing' in metallurgy or system 'reset' in computing (Carhart-Harris and Nutt, 2017; Carhart-Harris *et al.*, 2017c) where through enhanced excitability, the influence of prior beliefs is relaxed - as per a flattened energy landscape - so that new learning can occur.

> "Your assumptions are your window on the world, scrub them off every once in a while, or the light won't come in." (Isaac Asimov)

---

[7] N.B. Even though psychedelics have been shown to suppress raphe firing, the consequences of such firing are mimicked by direct serotonergic agonism via the psychedelic (Nichols, 2016).

9. Discussion

This article has revisited the so-called entropic brain hypothesis (Carhart-Harris *et al.*, 2014). It has cited increasing empirical support for the idea since it was originally published in early 2014 (Carhart-Harris *et al.*, 2014) and highlighted a particularly promising measure of brain entropy, Lempel-Ziv, that has proved to be informative about conscious level in disorders of consciousness (Casali *et al.*, 2013), pharmacologically induced loss of consciousness (Schartner *et al.*, 2015; Zhang *et al.*, 2001) and psychedelicinduced consciousness 'enrichment' (Schartner *et al.*, 2017). It has attempted to tackle the question of *what* increased entropy in the brain relates to in terms of conscious experience, proposing that richness of conscious experience, *information content* and *subjective uncertainty* are all close relatives - if not direct counterparts - of increased brain entropy (at least within a critical zone). Specific challenges for the entropic brain theory, and ideas about how it may be tested and advanced, were discussed. Two specific examples were provided of how the entropic brain might be clinically applied, i.e. through using psychedelics to facilitate emotional insight and/or treat disorders of consciousness. The former may be likened to the use of free-association in psychoanalysis, where an open, free-flowing mindstate is encouraged so that the likelihood of spontaneous insight is enhanced. Closing sections focused on properties of criticality in the brain and how these may be accentuated under psychedelics (Atasoy *et al.*, 2017) as well as recent advances in serotonin research that chime well with *the entropic brain* and may be usefully combined with it to solve a major riddle in psychopharmacology, namely *what is brain serotonin for*? The proposed solution being: to differentially encode behavioural responses to uncertainty. See (Carhart-Harris and Nutt, 2017) for a more focused discussion of this matter.

Like the original entropic brain paper (Carhart-Harris *et al.*, 2014), this updated version can be considered speculative and forward looking. This approach is vulnerable to critique (Papo, 2016) but may also be a strength. It is worth reflecting that the major arguments and hypotheses of the original entropic brain paper have stood up well to empirical scrutiny, e.g. that brain entropy is enhanced under psychedelics (Lebedev *et al.*, 2016; Schartner *et al.*, 2017; Tagliazucchi *et al.*, 2014; Viol *et al.*, 2017) and that the 'psychedelic-brain' exhibits more pronounced signatures of criticality than normal waking consciousness (Atasoy *et al.*, 2017).

It may be noted however, that some of the themes and terminology used in the original paper, e.g. 'primary and secondary consciousness', 'the ego' and the default-mode network, have been omitted from the present contribution. There is no conscious agenda behind this, other than a desire to focus on the most pertinent and timely topics, done in the interests of parsimony and concision. What is left out of the present paper should not be considered 'retracted' but rather side-stepped for the time being, in the interests of expediency. It should be clearly stated however, that the position that psychedelic research offers a unique opportunity for major principles of psychoanalytic theory to be tested, verified and revived is still very much maintained. There is a door ajar here for psychoanalytically-minded experimental psychologists and neuroscientists to open and walk through.

> "Until you make the unconscious conscious it will direct your life and you will call it fate." (Carl Jung)
>
> "These substances [psychedelics] function as unspecific amplifiers that increase the energetic niveau in the psyche and make the deep unconscious dynamics available for conscious processing. This unique property of psychedelics makes it possible to study psychological undercurrents that govern our experiences and behaviors to a depth that cannot be matched by any other methods and tools available in modern mainstream science." (Stanislav Grof)

Briefly, one specific hypothesis contained in the original paper (Carhart-Harris *et al.*, 2014) that has not stood the test of time, can now be revised, namely that the brain during seizure is sub-critical in relation to normal waking consciousness; in fact, evidence suggests it is super-critical (Meisel *et al.*, 2012) - which, with the benefit of hindsight, makes much more sense.

About the specific limitations of the present paper, it has been selective in its focus, and unlike the original (Carhart-Harris *et al.*, 2014), has said little about other altered states of consciousness in which entropy may be elevated above the normal waking baseline. Befitting its richer content and emotional tone, it has been shown that REM sleep is more entropic than NREM sleep (Abasolo *et al.*, 2015; Burioka *et al.*, 2005) but what about psychosis? The variegated nature of this disorder means we must be cautious about making too general and therefore misleading statements about it. For example, we can speculate that whereas entropy/uncertainty/content may be elevated in manic states (e.g. see Thomasson *et al.*, 2002) and early and acute psychotic episodes, it may be suppressed once a fixed delusion has formed - and/or an antipsychotic and/or mood-stabilising medication is introduced and becomes effective - for example see (Méndez *et al.*, 2012) for evidence of decreased brain entropy after treatment with mirtazapine for depression.

Also, while the literature is replete with studies applying entropy/complexity measures to EEG data recorded in the context of anaesthetics and sedatives, it is surprisingly difficult to find studies in which the same measures have been applied to EEG data recorded after acute administration of a stimulant (although see - Sun *et al.*, 2007). Stimulants would be particularly interesting controls for psychedelics, in terms of demonstrating the specificity of the proposed relationship between brain entropy and richness of conscious experience and subjective uncertainty. Until such comparisons are made, it is not possible to reject the possibility that brain entropy is merely an index of "alertness" or "arousal" - as has been suggested previously (Mateos *et al*. 2018) - although indirect evidence tentatively suggests that this alternative explanation is not compelling (Sun *et al.*, 2007; Liu *et al.*, 1997; Zarjam *et al.*, 2012). It seems more reasonable to suppose however, that altered states of consciousness induced by non-serotonergic psychedelics, deliriants and/or dissociatives, that share some of the phenomenological features the classic serotonergic psychedelics, e.g. enriched and changeable contents of consciousness and a sense of uncertainty, might also exhibit heightened entropic brain activity, as was recently demonstrated with the NMDA receptor antagonist ketamine for example (Schartner *et al.*, 2017).

Another limitation of the present paper is that although explicit mention has been given to the Lempel-Ziv measure (Schartner *et al.*, 2015), only general statements about it have been made - for greater detail see (Schartner *et al.*, 2015; Zhang *et al.*, 2001). For example, perhaps there are reasons to focus on the compressibility of signals detected from specific spatial locations when studying specific subjective phenomena (e.g. occipital sensors and visual phenomena) or to improve the temporal precision of our sampling so as to more accurately map between neurophysiological and phenomenological events or epochs - as discussed above. It is hoped that more nuanced hypotheses arising from the entropic brain theory can be tested in the future.

rain theory can be tested in the future. Relatedly, brain entropy has been treated here as a global brain phenomenon but there are reasons to be believe that spatial localisation is relevant to both the action of psychedelics and the neurobiology of consciousness. For example, the serotonin 2A receptors that appear to be the key trigger receptors for the psychedelic experience (Nichols, 2016) have their densest expression in high-level cortical regions belonging to the default-mode network (Beliveau *et al*. 2017) and this network, as well as other fronto-parietal networks, have been closely implicated in consciousness regulation (Guldenmund *et al.*, 2016) - as they have in the psychedelic state (Tagliazucchi *et al.*, 2016b; Carhart-Harris *et al.*, 2016b).

Another key issue deserving of focus before closing, is the matter of the relationship between entropy and criticality. It seems reasonable to infer that such a relationship exists but nothing specific has yet been said about this. Is it more accurate to describe the psychedelic brain as 'critical' or 'dynamically instable' than 'entropic'? Is there a limit to the rule that increased brain entropy relates to increased richness of conscious content? The answer to this last question is "probably yes", and more specifically, it seems likely that there is a zone of criticality (Moretti and Munoz, 2013) above which any further increases in brain entropy create a state of mind and brain that is incapable of integrating information into coherent 'wholes' (Gallimore, 2015). Anecdotal reports of complete and/or near-complete loss of consciousness under psychedelics can be found (https://erowid.org/experiences/) but are rare. Thus, generally speaking, the entropic brain principle, that increased brain entropy relates to an increased richness of conscious experience, may be said to stand, but only within an upper as well as a lower limit (Fig. 1). It is interesting to reflect that identifying the point at which conscious awareness is lost with psychedelics may be informative about consciousness itself - in the same way that anaesthetic-induced loss of consciousness has been well used to study consciousness so effectively. Questions about the ethics and safety of giving sufficiently high enough doses of psychedelics to achieve loss of consciousness may preclude this work from ever being done however - at least for the foreseeable future; although potent short-acting psychedelics such as DMT and 5-MeO-DMT may help surmount this issue. Another intriguing question is whether so-called "access consciousness" is more readily lost than "phenomenal consciousness" (Block, 2005) in the extreme, high-entropy psychedelic state.

Finally, but importantly, it must be conceded that applying entropy measures to brain physiology is not a new endeavour (Klonowski *et al.*, 1999; Nandrino *et al.*, 1994; Papo, 2016; Zhang *et al.*, 2001) and theories on the relationship between brain functional complexity and subjective experience have a history that should be properly acknowledged (Barttfeld *et al.*, 2015; Basar and Guntekin, 2009; Seth *et al.*, 2011; Tononi and Edelman, 1998; Tononi *et al.*, 1994). Perhaps the most influential theory on the brain basis of consciousness, is the so-called 'integrated-information theory' of consciousness (Tononi *et al.*, 2016), and this includes as one part of it, a measure of brain entropy/complexity. Indeed, it has been said in a critique of the original entropic brain paper that entropy/complexity measures applied to brain function merely 'depurate' the integration term from the integrated-information theory (Papo, 2016). This charge is readily accepted but the position is taken here that the entropy/complexity component of the integrated-information theory provides the major share of its explanatory power. This position is empirically substantiated, since it is arguably the complexity/entropy more than the integration measures per se that are so impressively predicting conscious level (Casali *et al.*, 2013; Casarotto *et al.*, 2016; Schartner *et al.*, 2015; Zhang *et al.*, 2001). While the requirement for integration is not disregarded (e.g. see the discussion on entropy and criticality in the previous paragraph) and may indeed by critical for access consciousness particularly - it is felt that the key properties of such integration, necessary for consciousness, have not yet been clearly delineated - although see the Global Workspace theory (Baars, 1993) for an appealing model on the importance of integration to conscious experience, as well as more recent work on large-scale (Tagliazucchi *et al.*, 2016a) and long-range connectivity (Kotchoubey *et al.*, 2013). It also remains possible that a role for integration may be implied within entropy/complexity measures; for example, future work may discover the point or zone within which entropy exceeds a critical threshold at which no one coherent, large-scale spatiotemporal configuration can dominate the brain for a sufficiently long-enough for access consciousness to be possible.

All models are incomplete and the entropic brain is no exception - but it was conceived and intended to offer a simple and useful heuristic, enabling relatively seamless translations to be made between a quantitative measure of the richness of brain activity and the richness of subjective experience.

10. Conclusions

In summary, four years on from the publication of the original entropic brain hypothesis, the present paper has sought to reflect on its influence, reliability and future scientific and clinical value. The position is maintained that entropy represents a uniquely powerful bridging tool for human neuroscience that will enable a better understanding of the mind-brain relationship and mechanics of consciousness, including how we may treat its abnormalities.

Acknowledgements

Imperial College London's neuroscientific research with psychedelics has been funded entirely through charitable donations. In this regard, deserving special credit for their early and enduring support is the Beckley Foundation, and particularly its Founder and Director Amanda Feilding. The author is presently supported by the Alex Mosley Charitable Trust. He is deeply grateful to Professor David Nutt for his support for his research, and also grateful to Leor Roseman and Christopher Timmermann for reading and commenting on an earlier draft of this manuscript. Christopher Timmermann's comments on neurophenomenology and microphenomenology have been particularly helpful. The author would also like to acknowledge conversations with Enzo Tagliazucchi, Jacobo Sitt, Robert Leech and Gregory Scott regarding the idea of using psychedelics to elevate conscious content in disorders of consciousness. Conversations with Dr Scott (NIHR clinical lecturer) have been particularly advanced. This is a shared idea which we hope to pursue further in the future, pending funding and the relevant approvals.

Psychedelic drugs, including lysergic acid diethylamide (LSD) and other agonists of the serotonin 2A receptor (5HT2A-R), induce drastic changes in subjective experience, and provide a unique opportunity to study the neurobiological basis of consciousness. One of the most notable neurophysiological signatures of psychedelics, increased entropy in spontaneous neural activity, is thought to be of relevance to the psychedelic experience, mediating both acute alterations in consciousness and long-term effects. However, no clear mechanistic explanation for this entropy increase has been put forward so far. We sought to do this here by building upon a recent whole-brain model of serotonergic neuromodulation, to study the entropic effects of 5HT2A-R activation. Our results reproduce the overall entropy increase observed in previous experiments *in vivo*, providing the first model-based explanation for this phenomenon. We also found that entropy changes were not uniform across the brain: entropy increased in all regions, but the larger effect were localised in visuo-occipital regions. Interestingly, at the whole-brain level, this reconfiguration was not well explained by 5HT2A-R density, but related closely to the topological properties of the brain's anatomical connectivity. These results help us understand the mechanisms underlying the psychedelic state and, more generally, the pharmacological modulation of whole-brain activity.

Psychedelic drugs provide a privileged opportunity to study the mind-brain relationship, and promise to revolutionise some of our current mental health treatments[1-3]. While some aspects of the neurochemical action of psychedelics at the neuronal and sub-neuronal level are well known[4,5], our current understanding of their action at the whole-brain level is still very limited. A deeper understanding of the mechanisms that trigger the changes in conscious experience produced by psychedelics would greatly advance our knowledge of human consciousness, as well as therapeutic development of psychedelics.

At a subjective level, serotonergic psychedelics (including LSD, dimethyltryptamine [DMT] and psilocybin, among others) potentially modulate mood, cognition, perception and self-awareness. At a neurophysiological level, recent research has identified (among many) two particularly prominent signatures of the psychedelic state: an overall dysregulation of neural population activity, most clearly seen as suppression of spectral power in the alpha (8-12 Hz) band[6-8]; and an increase in the signal diversity of the neural activity, measured through the information-theoretic notion of entropy[9]. In particular, this acute entropy increase has been linked to both short- and long-term effects of the psychedelic experience, including certain aspects of the reported subjective experience[9] and subsequent personality changes[10].

Interestingly, the opposite effects have been reported for states of loss of consciousness, where a strong *decrease* in brain entropy has been repeatedly observed. This seems to be a core feature of loss of consciousness, generalising across states such as deep sleep[11], general anaesthesia[12], and disorders of consciousness[13]. Together, these facts are yielding converging evidence that entropy and related measures offer simple and powerful indices of consciousness.

Based on these findings, Carhart-Harris and colleagues have put forward the *Entropic Brain Hypothesis* (EBH) an entropy-based theory of conscious states[1,14]. The EBH proposes the simple, yet powerful idea that the variety of states of consciousness can be indexed by the entropy of key parameters of brain activity; or, in other words, that the richness of subjective experience is directly related to the richness of on-going neural activity, where richness can be defined most simply as diversity. Note that even when different states can be indexed by their corresponding diversity, we are not claiming that one state is more conscious than other. Therefore, investigating the neurobiological origins of such changes in brain activity is a key step in the study of altered states of consciousness.

Multiple experiments in humans and animal models have established that the mind-altering effects of psychedelics depend on agonism specifically at the serotonin 2A receptor (5HT2A-R)[15-17]. A recent simulation study involving whole-brain computational modelling confirmed that the topographic distribution of 5HT2A-R in the human brain is critical to reproduce the functional connectivity dynamics (FCD) of human fMRI data recorded under the acute effects of LSD[18]. Here we build upon this model to characterise the interplay between the entropy of brain signals, the distribution of 5HT2A receptors, and structural connectivity properties of the brain, with the overarching goal of explaining the sources of entropic effects, and thus altered consciousness, elicited by psychedelic drugs.

Results

We simulated whole-brain activity using the Dynamic Mean-Field (DMF) model by Deco *et al.*[19,20], using parameter values fit to reproduce the dynamics of fMRI recordings in humans during wakeful rest, as well as under the acute effects of LSD (see Supplementary Figure 1)[18]. The model consists of interacting pools of excitatory and inhibitory neural populations, coupled via long-range excitatory connections informed by the anatomical connectivity of the brain. The DMF model combines a theoretical model of neural and synaptic dynamics with two empirical sources of information about the human brain: the human connectome, i.e. DTI-estimated connectivity between the 90 regions of the AAL[21] atlas; and average 5HT2A-R expression across the human brain obtained with Positron Emission Tomography (PET) scans[22].

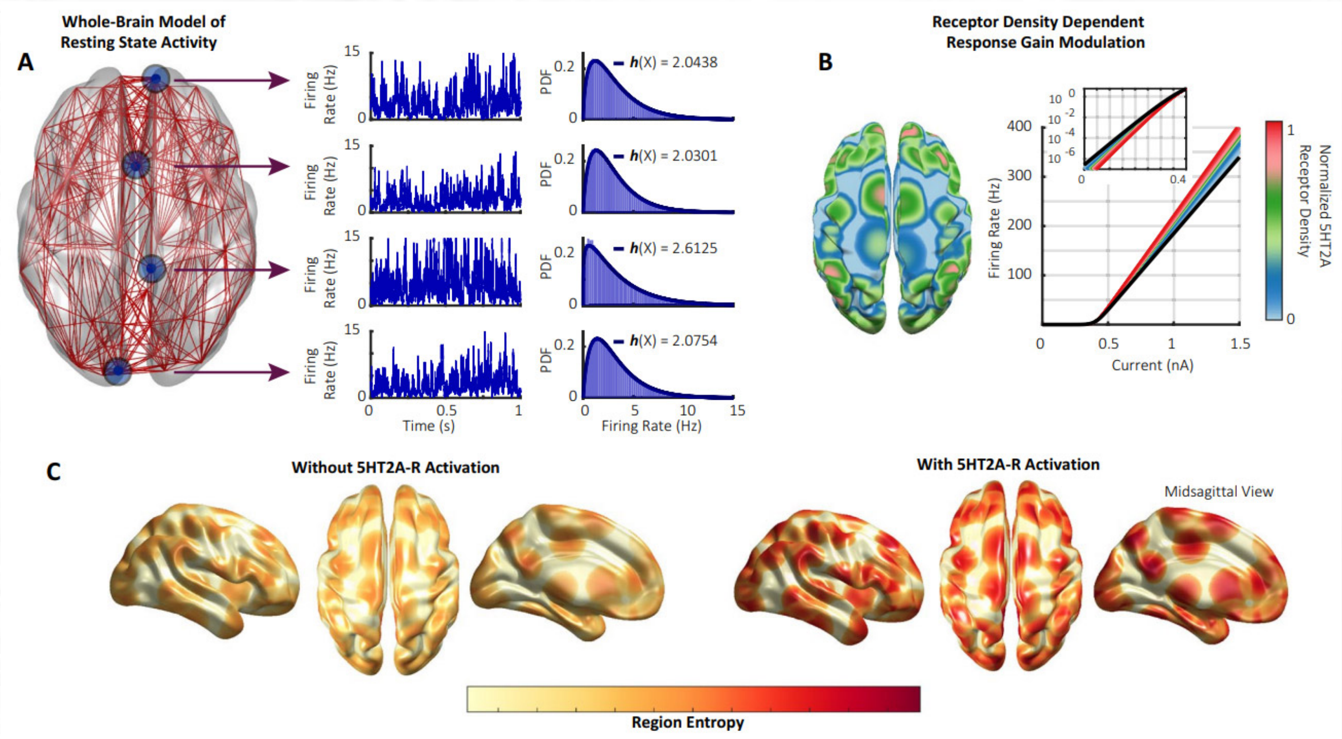

Figure 1. Modelling the effect of 5HT2A-R activation on the whole-brain topographical distribution of entropy. (**A**) Resting state activity is simulated using the dynamic mean-Field (DMF) model, in which each region's activity is represented by a time series of excitatory firing rates (constrained to 0-15 Hz for visualisation). The probability density function (PDF) and differential entropy ($\boldsymbol{h}$(X)) of each region is then estimated, obtaining a topographical distribution of entropy values. (**B**) 5HT2A-R agonism is modelled as a receptor-density-dependent response gain modulation. Black line is the frequency-current (F-I) curve of a population without 5HT2A-R agonism, and coloured curves show the resulting F-I curves of regions with increasing 5HT2A-R agonism. (**C**) 5HT2A-R activation changes the topographical distribution of entropy with respect to resting state activity, which constitutes the main subject of analysis in this study.

Each simulation of the DMF model generates 90 time series of excitatory and inhibitory firing rates, one of them for each region of the AAL atlas (Fig. 1A). These firing rates have a non-linear dependency on the local inputs, determined by a frequency-current (*F-I*) curve. Given that 5HT2A-R seems to modulate the sensitivity of neurons rather than driving them towards excitation or inhibition[4,23,24], we followed Deco *et al.*[18] and modelled 5HT2A-R activation as a response-gain modulation[25] of this F-I curve dependent on the receptor density at a given region (Fig. 1B).

We simulated the model in two conditions, with and without 5HT2A-R activation, which, in an analogy with neuroscientific terminology, we refer to as placebo (PLA) and 5HT2A-R conditions, respectively. In this way, we obtain 90 time series of excitatory firing rates for each condition, which we keep for further analysis.

Finally, using these time series, we estimate Shannon's differential entropy for each region under both conditions, yielding a topographical distribution of entropy values (Fig. 1C) that constitutes the main subject of analysis in this study. Further details about model specification and entropy estimation, as well as other methodological caveats, are presented in the Methods section at the end of this article.

5HT2A-R activation causes a heterogeneous, linear increase in the entropy of simulated brain activity. In our first analysis, we used the DMF model to test the main prediction of the EBH: that 5HT2A-R activation causes an increase in the overall entropy of neural signals (Fig. 2). In line with previous experimental findings with psychedelic drugs[9], the model shows a significant increase in the brain's entropy h due to 5HT2A-R activation, with an average entropy of $h^{\mathrm{PLA}} = 2.15$ nat in the placebo condition, and $h^{\mathrm{5HT2A}} = 2.25$ nat in the 5HT2A-R condition (dashed vertical lines in Fig. 2B, Wilcoxon signed-rank test $p < 10^{-6}$, Cohen's $d = 0.98 \pm 0.05$).

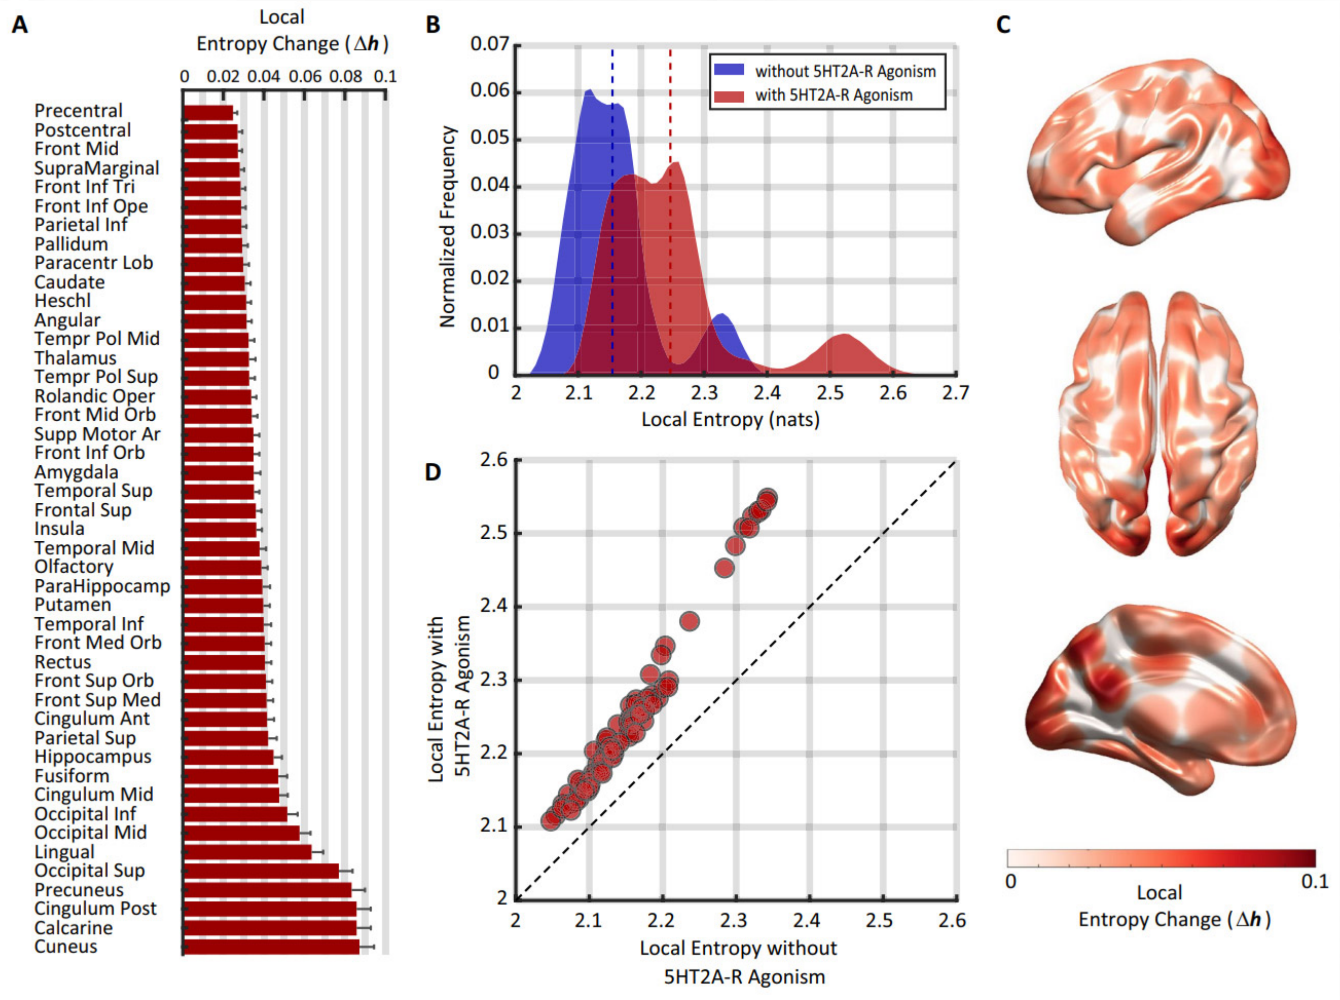

Figure 2. Linear heterogeneous increase of entropy following 5HT2A-R activation. (**A**) Effect of 5HT2A-R agonism on the local entropy each of region in the AAL atlas. See Supplementary Table 1 for abbreviations. Bars indicate the (bilateral) average relative change in local entropy, Δh_n, and error bars indicate 1 standard deviation across 1000 simulations. (**B**) Histograms of local entropy values for the condition with (red) and without (blue) 5HT2A-R activation. 5HT2A-R activation increased both the average and the spread of the local entropy distribution. (**C**) Topographical map of entropy changes. Brain regions are coloured according to their Δh_n values. (**D**) 5HT2A-R agonism changed the topographical distribution of entropy in linear manner. Each circle indicates the averages of each region across 1000 simulations.

A closer look at the distribution of entropy changes, however, reveals a more nuanced picture, entropy increases for all regions, but the effect is larger for visuo-occipital regions, compared to the rest of the regions (Fig. 2D, Supp. Fig. 2). This suggests that, according to the model, 5HT2A-R agonism might trigger a complex reconfiguration of the topographically specific distribution of entropy, and not a mere homogeneous overall increase.

To investigate this reconfiguration, we analysed the local changes in entropy by plotting the entropy of the nth region in both PLA and 5HT2A conditions, denoted by h_n^{5HT2A} and h_n^{PLA} respectively (Fig. 2D). Our results show that 5HT2A-R activation affects local entropy in a non-uniform and linear manner, especially in regions with high baseline resting state entropy. In particular, in such regions the effect of 5HT2A-R activation show a different tendency than the rest of the regions, such that the local entropy in the 5HT2A-R condition could not always be determined by the region's baseline entropy. This finding hints towards a more general theme: that local dynamical properties alone are not able to explain the local changes in activity induced by 5HT2A-R agonists like psychedelic drugs. We will explore this phenomenon in depth in the following sections.

Next, we studied the effect of 5HT2A-R agonism on local entropy by considering the relative change scores,

$$\Delta hn=hn5HT2A-hnPLAhnPLA\ .$$

Based on recent in vivo experiments with serotonergic psychedelics we expect to find localized entropy increases on occipital, cingulate and parietal regions[9,10] as well as several changes on regions belonging to Resting State Networks (RSNs)[7,26,27]. Accordingly, we split brain regions by standard anatomical and functional groupings, and found that the effect were localised specially in occipital areas, together with some cingulate and parietal regions. (Fig. 2A, Supp. Fig. 1). Additionally, regions participating in the primary visual and Default Mode (DMN) RSNs - including occipital and cingulate areas, respectively - showed a marked tendency to increase their entropy, as well as regions participating in the Frontoparietal Executive Network (FPN). Further discussion about the relation between these results and recent in vivo experiments with psychedelic drugs is presented in the Discussion section.

The topography of entropy changes is explained by local connectivity strength and 5HT2A-R density. Given the results above, and given the potential clinical and neuroscientific relevance of entropy reconfiguration in the psychedelic state, our next task is to elucidate what neurobiological factors underlie such phenomenon. In this section we investigate which structural and dynamical features of the model are able to predict local entropy changes due to 5HT2A-R activation, and what we can learn about the large-scale action mechanism of psychedelic drugs and other 5HT2A-R agonists.

To explain the effects of 5HT2A-R activation, the first natural step is to factor in the density of 5HT2A-R at each region. Somewhat surprisingly, at a whole-brain level, receptor density was a very poor predictor of the entropy change due to 5HT2A-R activation (Fig. 3A, $R^2 = 0.0053 \pm 0.0014$). In contrast, we found that the connectivity strength (based on the DTI human connectome), defined as the sum of all the weighted links connecting a given region, exhibited a moderate correlation with local entropy changes (Fig. 3B, $R^2 = 0.45 \pm 0.14$).

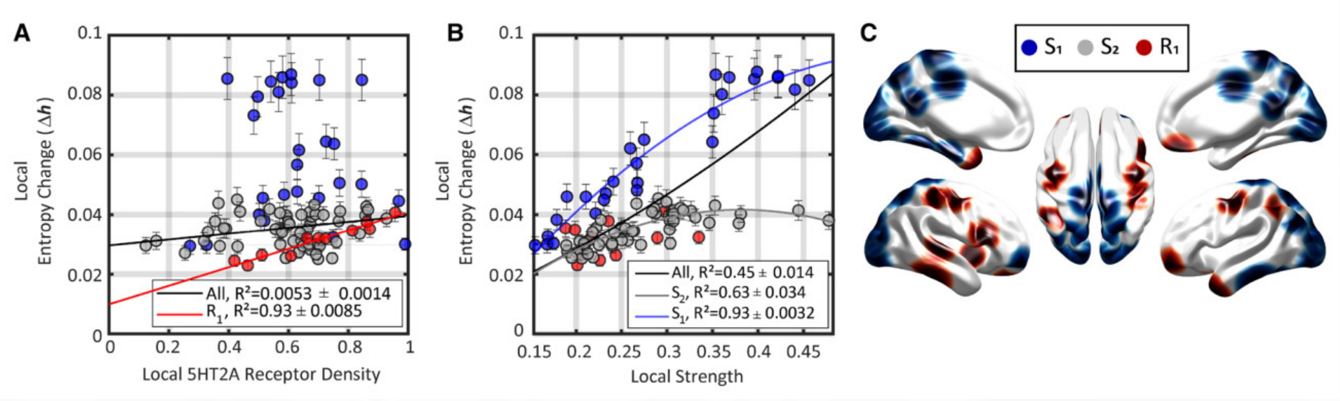

Figure 3. Changes in local entropy are explained best by connectivity strength, then receptor density. (**A**) Changes in entropy were overall independent from receptor density, although (**B**) they were well predicted by the connectivity strength of each region. We split into strength (blue and gray), and receptor dependent groups (red). The S_1 and S_2 groups showed no significant relationship with receptor density, while the R_1 group were highly correlated with it. (**C**) Topographical localisation of the three groups, following the same colour code. S_1 were mainly located in occipital, parietal and cingulate regions, while the R_1 ones were in temporal and frontal ones.

By visual inspection, however, it is clear that the relationship between DTI-informed connectivity strength and Δh_n is complex and can be split in two separate tendencies. To investigate this phenomenon, we implemented a simple optimisation algorithm to find the set of regions with the strongest relationship between strength and Δh_n. Tis yielded a set of regions with a higher strength-Δh_n correlation (S_1, $R^2 = 0.93 \pm 0.0032$, as opposed to $R^2 = 0.45 \pm 0.14$ for the whole-brain), and induced a partition of all brain regions into three groups: those highly dependent on strength (S_1, 27 regions, blue in Fig. 3A), those less dependent on strength (S_2, 42 regions, gray), and those highly dependent on receptors (R_1, 11 regions, red).

Building up on this partition, we studied the effect of receptor density on those regions where entropy change could not be predicted from connectivity strength - the R_1 group. We found a strong relationship between receptor density and entropy changes for the R_1 group, which resulted in positive correlation ($R^2 = 0.93 \pm 0.0085$). On the contrary, receptor density does not predict entropy changes for areas in the S_1 and S_2. This shows a complementary role of density and strength in S_1, S_2, and R_1 regions: entropy changes in R_1 regions strongly depend on the receptor density, but not connectivity strength; while changes in S_1, S_2 regions depend on connectivity strength, but not receptor density.

Overall, to assess the predictive power of connectivity strength and the receptor density on local entropy changes, we built a linear mixed model for Δh_n using connectivity strength, 5HT2A-R density, and the aforementioned three-way separation of brain regions as the predictor variables. Together these variables explain $94.5 \pm 0.002\%$ of the variance of Δh_n, confirming that they provide an accurate model for predicting the entropic effects of 5HT2A-R activation. This suggests that psychedelic drugs and other 5HT2A-R agonists do not have a simple, localised effect on brain activity, but instead amplify the fundamentally collective, emergent properties of the brain as a complex system of interacting elements.

The specific connectivity strength distribution explains relative changes in entropy. As a final analysis, we set out to investigate exactly which topological properties of the brain's structural connectivity explain the observed changes in entropy. With this exercise, we aim to answer two questions: whether any property simpler than connectivity strength *can* explain the results; and whether any property more complicated than connectivity strength is *needed* to do so.

To this end, we ran further simulations of the DMF model using suitable null network models of the human connectome (Fig. 4A), with the 5HT2A-R density map held fixed. In particular, we used three null models designed to test increasingly strict null hypotheses that preserved different network attributes of the original connectome: (1) the overall density and strength (RAND, Fig. 4B), (2) the degree distribution (degree-preserving randomisation [DPR], Fig. 4C); and (3) the strength distribution (strength-preserving randomisation, [DSPR], Fig. 4D). We simulated the DMF model in these surrogate networks, with and without neuromodulation, and computed the resulting entropy changes Δh_n.

Our first result is that random and degree-preserving surrogate networks are unable to reproduce the entropy changes observed in the human connectome: when compared against the Δh_n values obtained from the unperturbed network, neither of them produce values close to the original (Fig. 4E,F). This result asserts the findings in the previous section, showing that indeed node strength plays an important role in shaping the global pattern of entropy change associated with the action of psychedelics and other 5HT2A-R agonists. Simpler topological features, like the degree distribution, are not enough to explain such changes.

Perhaps more interestingly, the connectivity strength-preserving surrogate networks partially reproduced the entropy changes, suggesting that higher-order properties of the connectome are necessary (Fig. 4G). Furthermore, we repeated the analyses in the previous section trying to predict Δh_nusing other local connectivity measures (e.g. betweenness, eigenvector centrality), and none of them produced a model as accurate as strength (Supp. Fig. 2). Together, these results show that, once the receptor distribution is fixed, the network strength distribution is both *necessary* but not *suffcient* to explain the entropic effects of 5HT2A-R activation.

As previously suggested, other topological network features are known to mediate transitions of consciousness in other contexts[28], and investigating which network properties explain high-order dynamical signatures[29] of psychedelics remains an exciting avenue of future work.

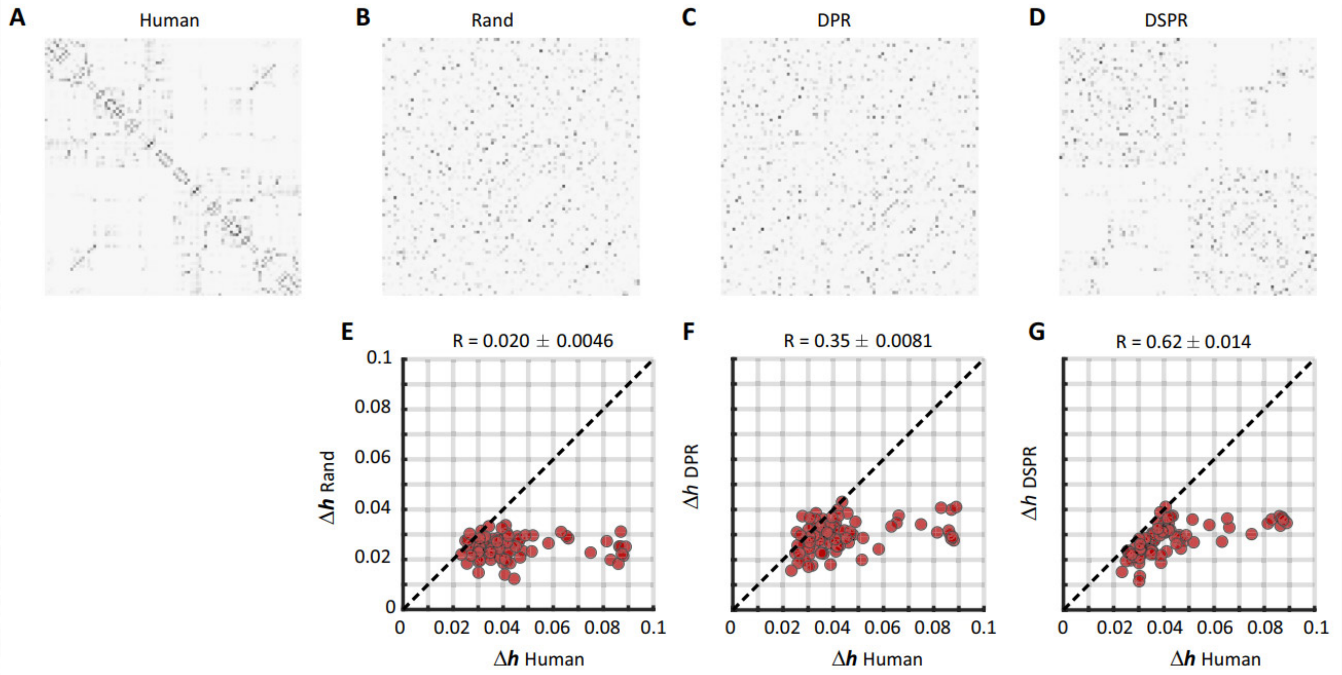

Figure 4. Relative changes in entropy are partially reproduced by a strength-preserving null model of the connectome. (**A-D**) Connectivity matrices used to control the role of local properties of the connectome on Δh_n. See main text for the description of the matrices and randomisation algorithm. (**E-G**) Scatter plots of Δh_n for the human connectome against the three null models. DSPR yielded a high but not perfect correlation showing that local network properties of human connectome are necessary but not suficient to capture the effect of 5HT2A-R activation.

Discussion

In this study, we investigated the brain entropy changes induced by serotonergic psychedelics by simulating whole-brain resting state activity with and without 5HT2A-R activation. In contrast to empirical studies, which usually only have access to coarse-grained fMRI or M/EEG data, our approach allows us to study firing rates of brain regions and hence to directly assess the effect of 5HT2A-R agonism at the level of neural population activity.

In agreement with the Entropic Brain Hypothesis[14], the model shows a significant increase of global brain entropy, with a inhomogeneous and linear reconfiguration. The diversity of effects stresses the importance of extending the scope of the EBH from a simple level-based approach towards a multi-dimensional perspective, which might better characterise the richness of 5HT2A-R activation effect both on the brain and consciousness.

We propose a possible mechanism in the sense that the average increase in neural entropy induced by serotonergic psychedelic drugs can be explained (in statistical sense) in terms of quantities that provide a neurobiological interpretation about how this phenomena could occur in the brain. These results have important consequences for our understanding of consciousness, neurodynamics, and the psychedelic state. In the following, we highlight some of those implications, and propose possibilities for future work.

5HT2A-R-induced entropy changes are regionally heterogeneous. Our main result in this study is a mechanistic explanation of the main prediction of the EBH that serotonergic psychedelics increase the entropy of brain activity. However, one of the main takeaways is that this overall increase is tied to a spatially heterogeneous reconfiguration, rather than a globally consistent increase, in entropy.

Our simulation results show that 5HT2A-R activation triggers an entropy increase in sensory areas, as observed in occipital cortices, as well as the primary visual RSN (Supp. Fig. 2). This agrees with the increased perceptual 'bandwidth' that characterises the psychedelic state[30], as higher entropy might be related to richer perceptual experience in a given moment of consciousness - potentially related to reduced gating. As a matter of fact, all the primary visual RSN regions are part of the S_1 group, suggesting that the effect of psychedelics on perceptual experience might be directly related to the connectivity of those regions. The localisation of the entropy increases may relate to domain-specific changes in consciousness, which could be interpreted as consistent with a recent dimensions of consciousness characterisation of the psychedelic experience[31].

Comparison to *in vivo* experiments with psychedelic drugs. Throughout the paper, we have focused on one particular signature of 5HT2A-R agonists on the brain - a global increase in average entropy. But much more is known about the effect of psychedelics on the brain, and studying these more nuanced effects is key to understanding the rich phenomenology of the psychedelic state. In this section we deepen this connection by providing a more detailed comparison between the behaviour of the model and experimental results with psychedelic drugs.

Our findings are in agreement with earlier studies where the effect of psychedelic drugs on the topographical distribution of entropy-related measures was correlated with subjective effects. For example, Schartner *et al.*[9] studied the effect of LSD, psilocybin, and ketamine on the entropy rate of binarized MEG signals, and found localised increases in entropy rate on occipital and parietal regions. Similarly, Lebedev *et al.*[10] analysed the sample entropy of fMRI recordings of subjects under the effect of LSD, finding localized increases on frontoparietal, medial occipital, posterior and dorsal cingulate regions. Many of those regions showed a consistent increase of their entropy with 5HT2A-R agonism in our study (Fig. 2A).

Moreover, many of those regions actually belong to the S_1 group (c.f. Fig. 3), which suggests that their entropy increase in experimental data might be directly related to the connectivity in those regions.

Together, these findings support the conclusion that the DMF model, once optimised, can reproduce not only functional connectivity[18], but also some of the most salient localised entropy increases found on in vivo human studies up to date.

Also, on a more fundamental level, our findings suggest that psychedelics disrupt the functional organisation of the brain with an especially focal and pronounced action on highly anatomically connected brain regions. In fact, experimental and modelling evidence points towards a key role of connector hubs on psychedelic and psychopatological states[32,33].

Perturbing the activity in these specific regions (via 5HT2A-R agonism) could have particularly profound implications for the regularity of brain activity and the quality of conscious experience. However, sub cortical regions may also play an important role on the modulation of brain activity, conscious experience, and the psychedelic state[34].

On a separate line of inquiry, there is strong evidence associating the DMN to high-level cognitive functions, including the sense of space, time and recognition of (self) boundaries.

Disruptions to the DMN have been linked to fundamental changes in experience, such as ego dissolution[14,35]. Our simulation results show that 5HT2A-R activation increases the entropy of all DMN regions, which is consistent with the reported decrease in the DMN network integrity[32] induced by psychedelic drugs. In contrast, low-level motor functions such as motor regulation remain largely unaffected during the psychedelic state[36], which is consistent with the modest entropy changes observed in the lingual and superior motor areas.

Current limitations and future research. The approach employed in this work presents certain limitations related to several aspects of the simulation and analysis. Acknowledging and understanding these limitations can help us extend and improve our approach, while introducing new questions in the field of psychedelic computational neuroscience.

To our knowledge, the DMF model is the only whole-brain model that implements neuromodulation and is capable of reproducing neuroimaging data in the placebo and psychedelic states. Nonetheless, it makes some important simplifications that are worth discussing. At the network level, the DTI-based connectome used here is known to be incomplete, thus improvements could be made to the model parameters of brain connectivity[37]. At the dynamical level, the DMF model models neuronal populations as perfectly homogeneous within a given region, and it is known that finer-grained local structure of certain brain regions is likely to be key to explaining certain subjective effects of the psychedelic state (e.g. lattice structure in the visual cortex and geometric visual hallucinations[38]). Additionally, the version of the DMF model used here only considers 5HT2A-

R agonism, while classic serotonergic psychedelic drugs also have high binding affinities for other receptors (e.g. in the case of LSD, the D1 and D2 dopamine receptors[39]).

These simplifications do not prevent the model from reproducing statistical features of brain signals under the placebo and 5HT2A-R conditions, but could result in an inability to reproduce finer aspects of the dynamics of the whole-brain activity in these conditions. Extending the model to reproduce other dynamical signatures of psychedelics (like alpha suppression[8] or reduced directed functional connectivity[40]) constitutes a natural extension of this work, with the recent example of Kringelbach *et al*.[41] where an extension of the DMF can reproduce dynamical features of the brain in placebo and in the psychedelic state.

Another potentially fruitful line of future work involves making more detailed comparisons with in vivo psychedelic neuroimaging data, and, potentially, subjective experience reports. For example, one natural option would be to use forward models of fMRI[42] or M/EEG[43] to bridge between the firing rates produced by the DMF model and other data modalities, to produce simulated data that is more directly comparable with available empirical data.

Another exciting possibility is to explore model parameters to examine potential non-linearities and their implications for different relevant aspects of brain function. For example, there are reasons to believe that the dose-response relationship is non-linear for psychedelics and that over a certain threshold dosage (level of 5HT2A-R stimulation) new subjective and global brain function properties can appear[44].

Most interestingly, a potentially very useful extension of this work would be to include individual subject-level connectome and receptor data to build personalised models of response to psychedelic drugs. This would enable a much more comprehensive modelling framework, capable of correlating structural brain features with subjective experience reports. Such a framework could potentially make individualised predictions of the action of serotonergic psychedelics on specific individuals, aiding patient stratification and treatment customisation[2].

Finally, it is worth noting that all our analyses here are based on the univariate statistics of individual brain regions, not including any correlation or information flow between them. However, it is known that some high-level subjective effects of psychedelics (such as complex imagery[7] and ego dissolution[35]) are related to network, as opposed to single region, dynamics. Therefore, building a richer statistical description of the brain's dynamics using recent information-theoretic tools (such as multivariate extensions of mutual information[29] or Integrated Information Theory, IIT[45]) remains an exciting open problem. In fact, recent attempts of unifying IIT and the EBH in a single framework to understand the effects of psychedelic drugs[46] are helping to bridge the gap between the univariate EBH and the multivariate IIT.

Final remarks

In this paper, we have provided the first mechanistic explanation of the neural entropy increase elicited by psychedelic drugs, using a whole-brain dynamical model with 5HT2A-R neuromodulation. Furthermore, we built a simple model able to predict a region's relative change in entropy from its local 5HT2AR density and topological properties, showing that, somewhat paradoxically, at a whole-brain level receptor density is a poor predictor of 5HT2A-R activation effect.

Key to developing this predictive model was a three-way partition of brain regions according to the dependency they exhibited with connectivity strength, suggesting a differentiated action mechanism of 5HT2A-R agonists that depends on the local topology of brain regions. In summary, our results suggest that the local changes in entropy, as well as the global entropy increase, induced by 5HT2A-R activation can be explained from a region-specific interplay between structural connectivity and receptor density. Finally, controlled experiments with null network models confirm that receptor density and connectivity strength are necessary, but not sufficient, to explain the entropic effects of 5HT2A-R activation.

Te spatially heterogeneous, complex nature of the observed effects of 5HT2A-R activation opens a challenging problem for understanding the clinical and scientific relevance of psychedelic drugs and their entropic effect. Furthermore, it stresses the necessity of moving beyond the current unidimensional approach to consciousness to a multi-dimensional one, that better captures the phenomenological and neurodynamical richness of psychedelic state.

Methods

Dynamic mean-field model with 5HT2A-R neuromodulation. The main computational tool used in this study is the Dynamic Mean-Field (DMF) model by Deco *et al.*[18,19] which consists of a set of coupled differential equations modelling the average activity of one or more interacting brain regions. In this model, each brain region n is modelled as two reciprocally coupled neuronal masses, one excitatory and one inhibitory, and the excitatory and inhibitory synaptic currents $I^{(E)}$ and $I^{(I)}$ are mediated by NMDA and GABA$_\text{A}$ receptors respectively. Different brain regions are coupled via their excitatory populations only, and the structural connectivity is given by the matrix C.

The full model, including the neuromodulatory effect described below, is given by

Above, for each excitatory (E) and inhibitory (I) neural mass, the quantities $I_n^{(E,I)}$, $r_n^{(E,I)}$, and $S_n^{(E,I)}$ represent its total input current (nA), firing rate (Hz) and synaptic gating variable, respectively. The function $F(\cdot)$ is the transfer function (or *F-I curve*), representing the non-linear relationship between the input current and the output firing rate of a neural population. Finally, J_n^{FIC} n is the local feedback inhibitory control of region n, which is optimized to keep its average firing rate at approximately 3 Hz (Supp. Fig 1), and v_n is uncorrelated Gaussian noise injected to region n. The interested reader is referred to the original publication for further details[19].

Key to this study is the recent extension of this model including neuromodulatory efects[18]. In the equations above, g_n^{NM} is a *neuromodulatory scaling factor* modulating the F-I curve of all brain regions in the model, which affects region n depending on its density of the receptor of interest, d_n^{rec}. Including neuromodulation, the free parameters of the model are G, the global coupling parameter, and s_{NM}, the neuromodulatory gain, that are set to 2.4 and 0.025, following our fitting procedure (Supp. Fig. 1). To simulate the expression of 5-HT$_{2A}$ receptor on the excitatory and inhibitory populations[47], neuromodulation was applied to both populations. The model was simulated using a standard Euler-Maruyama integration method[48], using the parameter values shown in Table 1.

Parameter	Symbol	Value
External current	I_0	0.382 nA
Excitatory scaling factor for I_0	W_E	1
Inhibitory scaling factor for I_0	W_I	0.7
Local excitatory recurrence	w_+	1.4
Excitatory synaptic coupling	J_{NMDA}	0.15 nA
Treshold for $F(I_n^{(E)})$	$I^{(E)}_{thr}$	0.403 nA
Treshold for $F(I_n^{(I)})$	$I^{(I)}_{thr}$	0.288 nA
Gain factor of $F(I_n^{(E)})$	g_E	310 nC^{-1}
Gain factor of $F(I_n^{(I)})$	g_I	615 nC^{-1}
Shape of $F(I_n^{(E)})$ around $I^{(E)}_{thr}$	d_E	0.16 s
Shape of $F(I_n^{(I)})$ around $I^{(I)}_{thr}$	d_I	0.087 s
Excitatory kinetic parameter	γ	0.641
Amplitude of uncorrelated Gaussian noise v_n	σ	0.01 nA
Time constant of NMDA receptor	τ_{NMDA}	100 ms
Time constant of GABA-A receptor	τ_{GABA_A}	10 ms

Table 1. Dynamic mean field (DMF) model parameters.

Parcellation, connectome, and 5HT2A receptor maps. In addition to the DMF equations above, to simulate whole-brain activity we need three more ingredients: a suitable parcellation of the cortex into well-defined regions, a structural connectivity matrix between those regions, and the density map of a receptor of interest - in our case, the serotonin 2A receptor. We clarify that all the empirical inputs of the model were produced elsewhere. For a detailed description of the procedure, please follow the corresponding references cited below.

As a basis for our simulation, we used the Automated Anatomical Labelling (AAL) atlas[21], a sulci-based parcellation of brain volume registered in MNI space. The AAL parcellation specifies a partition of the brain into 90 Regions Of Interest (ROIs), that provides sufficient level of detail to obtain a picture of the topographical distribution of entropy, while being suitable for computationally intensive simulations.

Structural connectivity data between the 90 AAL ROIs was obtained from 16 healthy subjects (5 female) using diffusion Magnetic Resonance Imaging (dMRI), registered to the MNI space and parcellated according to the AAL atlas on the subject's native space. Ten, for each subject the histogram of fiber directions at each voxel was obtained, yielding an estimate of the number of fibers passing trough each voxel. The weight of the connection between regions i and j was defined as the proportion of fibers passing through region i that reach region j, which (since the directionality of connections cannot be determined using dMRI) yields a symmetric 90 × 90 Structural Connectivity (SC) matrix. Finally, the SC matrix of each subject was thresholded, pruning any connection lower than 0.1%, and SC matrices of all subjects were averaged to obtain a single SC matrix used in all simulations. This average matrix was kindly provided by Deco *et al.*[18] For a detailed description of these methods see or refer to the Supplementary Subsection 7.

For the density map of 5HT2A receptors, we used the Positron Emission Tomography (PET) data made public by Beliveau *et al.*[22], which can be combined with the AAL parcellation to obtain an estimate of receptor density in every AAL region. Further details can be found in the original publications[18,22].

Together with the DMF equations, these three elements fully specify our whole-brain model and allow us to run simulations and obtain time series of excitatory firing rates, $r_n^{(E)}$, which we save for further analysis.

Estimating the differential entropy of firing rates. The result of each simulation is a set of 90 time series representing the firing rate of each excitatory population ($r_n^{(E)}$), which we analysed to measure the entropy of the activity of each ROI. For a continuous random variable X with associated probability distribution $p(x)$ and support X, its differential entropy is defined as[49]

$$h(X) = - \int_X p(x) \ln p(x) \, dx.$$

Estimating differential entropy from data is in general a hard problem, stemming (for the most part) from the difficulties in estimating a probability density from samples[50]. We found that the probability distributions of firing rates $r_n^{(E)}$ were well approximated by a gamma distribution: goodness-of-fit, measured with a standard Kolmogorov-Smirnov statistic, was satisfactory and comparable across brain regions and conditions (see Supp. Fig. 3).

This observation greatly simplifies the estimation of the differential entropy of each region, which is now reduced to estimating the shape and scale parameters of the gamma distribution, k and θ. Once these parameters are estimated (in our case by standard maximum likelihood estimation), the differential entropy of a gamma distribution can be computed analytically in closed form as

$$h(X) = k + \ln \Theta + \ln \Gamma(k) + (1 - k)\, \Psi(k),$$

where $\Gamma(\cdot)$ and $\Psi(\cdot)$ are the standard gamma and digamma functions, respectively.

Linear models for Δh_n and three-way separation of AAL regions. To explain the changes in differential entropy across regions and conditions, we trained several linear mixed-effects models[51] using different sets of covariates designed to test specific hypotheses about the relation between entropy, 5HT2A-R density, and network topology.

First, we implemented a simple algorithm to find the group of regions where the change in entropy depends on region strength. The model was fit by maximum likelihood using of-the-shelf software, and explanatory power measured using R^2. To do so, we designed an optimisation procedure to find the optimal fit between Δh_n and connectivity strength, using all occipital regions of the AAL90 atlas as a prior for a quadratic fit (i.e. the S_1 group). The rest of the regions were used for a linear fit between Δh_n and receptor density. Regions were assigned to the S_1 group if the residuals of the quadratic fit to strength were lower than the residuals for the linear fit to receptor density. An optimization algorithm randomly partitioned the remaining regions in two groups until a maximum in the R^2 of a linear mixed-effects model with 3 grouping variables (i.e. S_1, S_2, and R^2) is obtained. The model used a quadratic fit for strength-dependent regions, and a linear one for receptor-dependent regions.

This three-way separation of brain regions induces a model with 7 terms: a constant term and 2 fixed-effect terms for each group of regions: one for the connectivity strength and one for the receptor density.

Null network models of the human connectome. Null network models of the human structural connectivity were used to evaluate the role of the local connectivity properties[52,53] on the local changes in entropy induced by 5HT2A-R activation. To this end, we applied three different randomisation schemes to the structural connectivity in order to produce suitable surrogate networks. These surrogates were designed to preserve different network attributes of the original connectome: (1) the overall density and strength (RAND), (2) the degree distribution (degree-preserving randomisation [DPR]); and (3) the strength distribution (strength-preserving randomisation [DSPR]).

Afer randomisation, the DMF model was run with and without 5HT2A-R activation, and entropies estimated and analysed following the same procedure as in the rest of the article. Every surrogate model was run 120 times, and the results averaged across runs.

In addition to the network surrogates, we computed several topological measures to include in the linear model reported in Fig. 3. These measures included betweenness, eigenvector centrality, closeness, communicability, PageRank index, and sub-graph centrality. All of these computations, including the surrogate networks and the topology measures, were performed using the Brain Connectivity Toolbox[54].

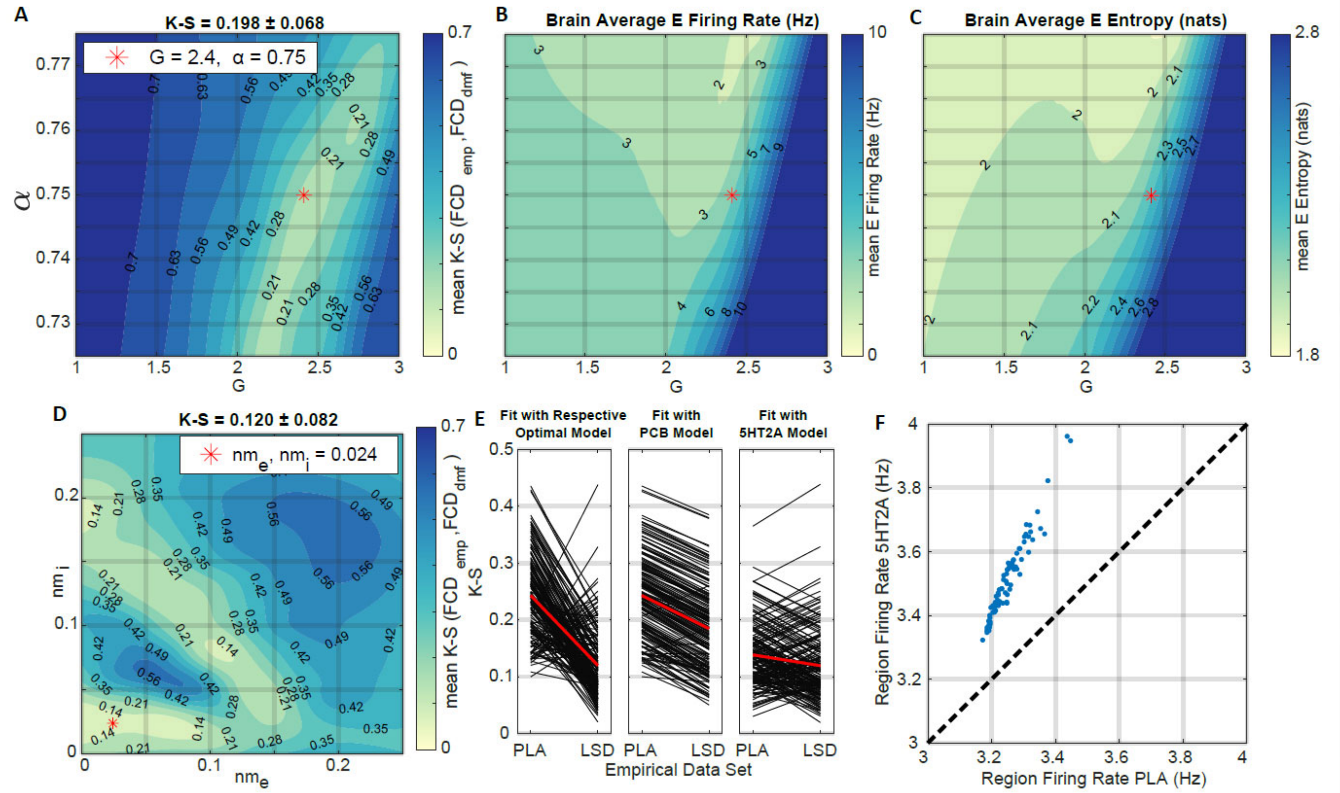
Supplementary Information

Subsection 1. Model fit to empirical BOLD data

A Bayesian optimization algorithm was implemented to simultaneously optimize the global coupling parameter G, and α, a global parameter that controls the local inhibitory feedback parameter. The cost function was defined as the Kolmogorov-Smirnof distance (K-S) between the empirical and the simulated functional connectivity dynamics (FCD) distribution. Resting state BOLD signals of the placebo condition were used to fit the model associated to the non-drug condition. The data set and processing was exactly the same than the one used in Ref.[1]. The optimization stopped after 10 consecutive iterations with improvements lower than 1%. The optimal average K-S (0.198 ± 0.068) was found at G=2.4 and α 1.5 (Supplementary Figure 1A), where also the average firing rates fell within the biologically plausible[2] 3-4 Hz range (Supplementary Figure 1B,F). Once the model was fit to the placebo data, the neuromodulatory gain for the excitatory (nm_E) and the inhibitory (nm_I) population were optimized such that the K-S of the FCD between the model and the data associated to LSD BOLD signals is minimized. There was several regions where the K-S were minimized (Supplementary Figure 1D), so, for simplicity, we only used solutions were both neuromodulatory had the same magnitude, obtaining an average K-S of 0.120 ± 0.082. Then, we compared the K-S values of the models fitted to their respective data sets (Supplementary Figure 1E), finding an improvement of the goodness of fit of the model with neuromodulation to LSD data.

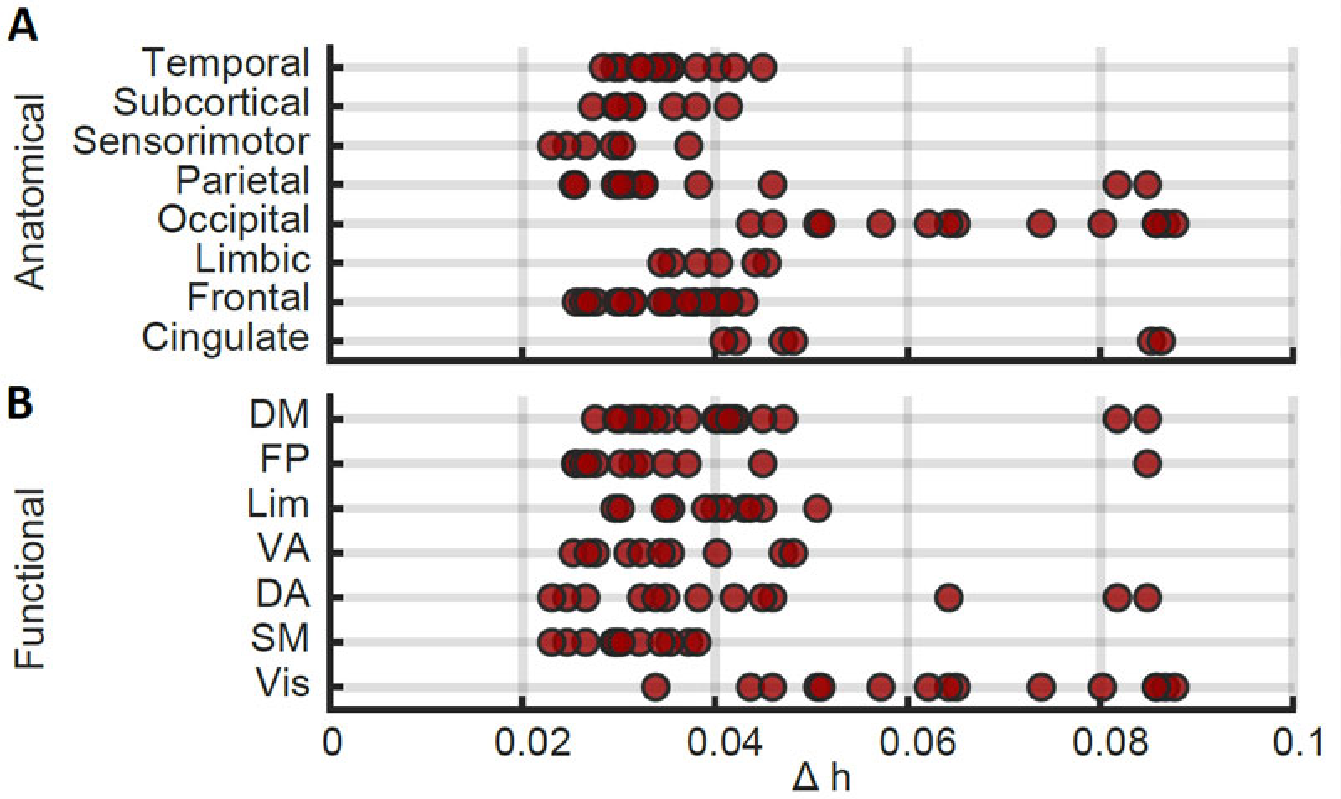


Supplementary Figure 1. Model fit to empirical BOLD data. (**A**) Estimated average K-S distance between the empirical FCD obtained from placebo resting state condition and the FCD obtained with the model. G and α were optimized by Bayesian optimization. The corresponding average excitatory firing rates, and entropies are shown in B and C, respectively. (**B,C**) Average firing rate and entropy for the excitatory pool, respectively, as a function of the two free parameters. (**D**) Estimated average K-S distance between the empirical FCD obtained from LSD resting state condition and the FCD obtained with the model with neuromodulation (5HT2A). nm_e and nm_i were optimized by Bayesian optimization. (**E**) Goodness of fit of models to their corresponding data sets, and cross-goodness of fit to data, i.e. using the placebo model for fitting LSD and the LSD model to fit placebo. The model with neuromodulation improves the goodness of fit to empirical LSD data, respect to the other comparisons. (**F**) Scatter plots of the excitatory firing rates in both simulated conditions.

Supplementary Subsection 2. Heterogeneous entropy changes induced by 5HT2A-R activation on anatomical and functional groupings of brain regions.

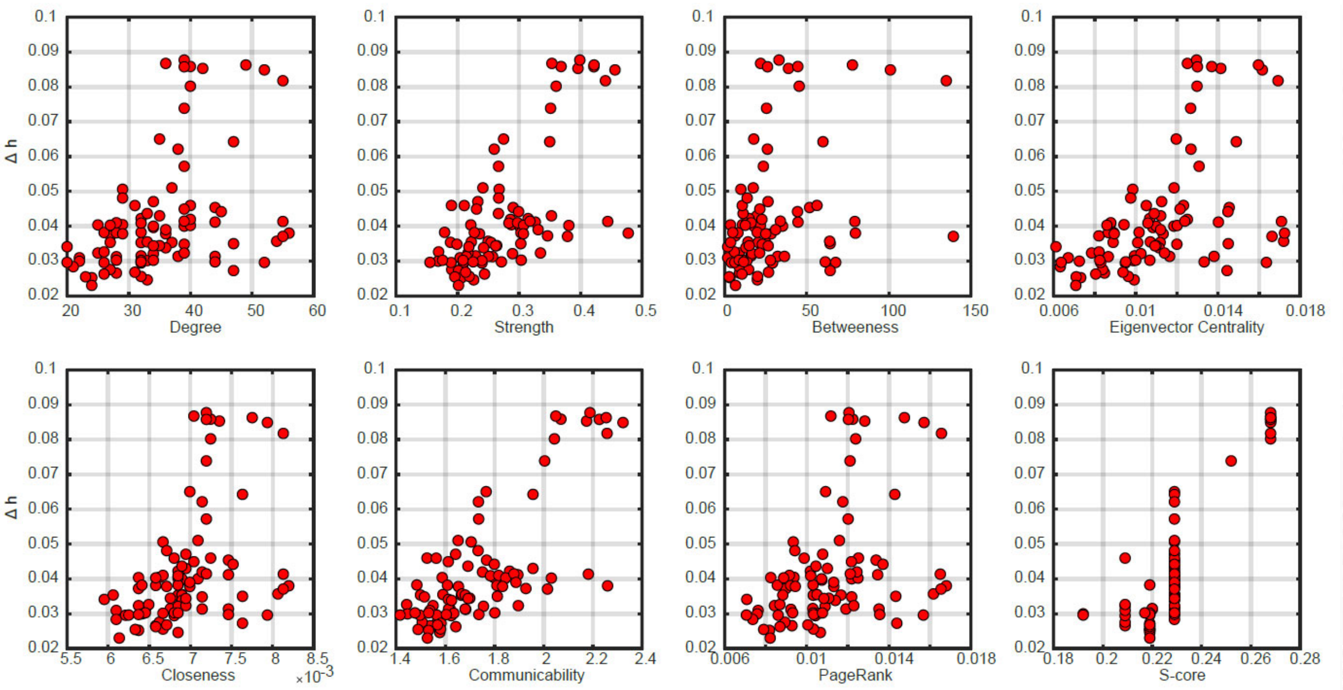
We asked whether the heterogeneous changes of entropy induced by 5HT2A-R activation could be explained by grouping the AAL brain regions according to anatomical and functional criteria. Regarding anatomical criteria brain regions can be spatially split into 8 major non-overlapping anatomical groups: Frontal, Temporal, Parietal, Occipital, Limbic, Sensorimotor, Cingulate and Subcortical.[3] Regarding the functional grouping, we used the Resting State Networks, a functional grouping of brain regions based on the observed spatio-temporal patterns of BOLD signals during resting state activity.[4] These groups are Salience (Sal), Fronto-Parietal (FPN), Default Mode (DMN), Primary Visual (Vis), Extrastiate Cortex (EC), Auditory (Aud), Sensorimotor (SM), and Executive Control (EC). The first one, Sal, was obtained from Lee *et al*.[5], the second and third, FPN and DMN, were obtained from Oliver *et al*.[6], and the rest from Beckmann *et al*.[4] Brain regions can potentially belong to different functional groups.

The effect of 5HT2A-R activation on entropy is heterogeneous also at the level of anatomical groups (Supplementary Figure 2A). However, Occipital and Cingulate regions show a strong tendency to increase their entropy, in agreement with entropy increases in these regions observed in human experiments with serotonergic psychedelics.[7, 8] Regarding the functional grouping (Supplementary Figure 2B), we also found that the effect of 5HT2A-R activation on regional entropy (Fig. 3B) is heterogeneous within groups. In particular, in the Vis networks showed the larger tendency to increase.



Supplementary Figure 2. The effect of 5HT2A-R activation is not explained by anatomical or functional groupings. (**A**) 5HT2A-R activation heterogeneously change entropy in regions belonging to the same anatomical group. (**B**) Entropy also changed in a heterogeneous way when functional grouping is considered. Note the special case of Vis network, which included region with larger increase. Circles are averages computed from 1000 simulations.

Supplementary Subsection 3. Connectivity strength is the best predictor for entropy changes among local connectivity measures. We control the role of local connectivity on the observed entropy changes (Δh_n) induced by 5HT2A-R activation using as predictors for Δh_n other local connectivity measures as: degree,[9] eigenvector centrality,[9] communicability,[10] page-rank,[9], closeness centrality,[11], and s-core[12]. Despite communicability exhibits a very similar pattern to strength, the latter has a simpler interpretation than the former. Thus, we confirmed that local connectivity strength is the best linear predictor of entropy changes among other centrality measures.

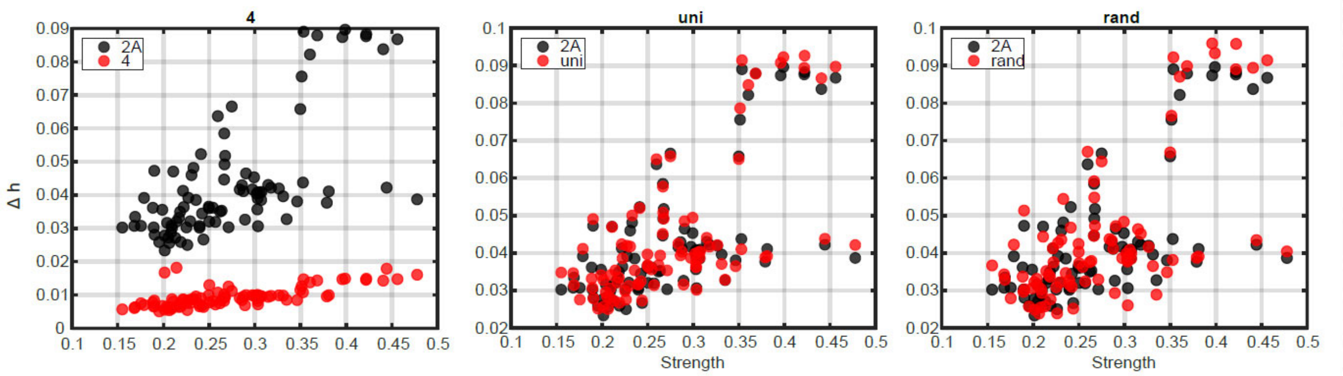


Supplementary Figure 3. Centrality measures as possible explanatory variables for Δh_n. Local connectivity strength is the best linear predictor of Δh_n among other centrality measures. Communicability also showed a good linear relationship with Δh_n, but strength has more interpretability in terms of the connectome. Circles are averages computed from 1000 independent simulations.

Supplementary Subsection 4. Receptors controls.

We controlled the role of receptor density distribution on the observed entropy changes (Δh_n) induced by 5HT2A-R activation by using alternative receptor distributions. To test the effect of the heterogeneous 5HT2A-R distribution on Δh_n, we used an uniform receptor distribution, where the receptor density for each region corresponds to the average 5HT2A-R density among all regions. To evaluate the role of the specific 5HT2A-R distribution, a randomised version of the 5HT2A-R was also used, where for each simulation the receptor expression is randomised. Finally, to evaluate the effect of activating other serotonin receptors, we used the 5HT4-R distribution, a receptor thought to play no role on the psychedelic state.

The Uniform and Random receptor distributions show almost the same complex behaviour than the 2A on average. The 5HT4-R distribution changes entropy but in a subtler manner, showing no complex dependency with the strength. On summary, the specific 5HT2A-R distribution does not impact critically on Δh_n values; rather, the average receptor density seems to capture most of the relationship with the connectivity strength. In addition, using other empirically-based distribution yields no significant change in average brain entropy, highlighting the key relationship between 5HT2A-R density and connectivity on the entropic effects induced by serotonergic psychedelic drugs.

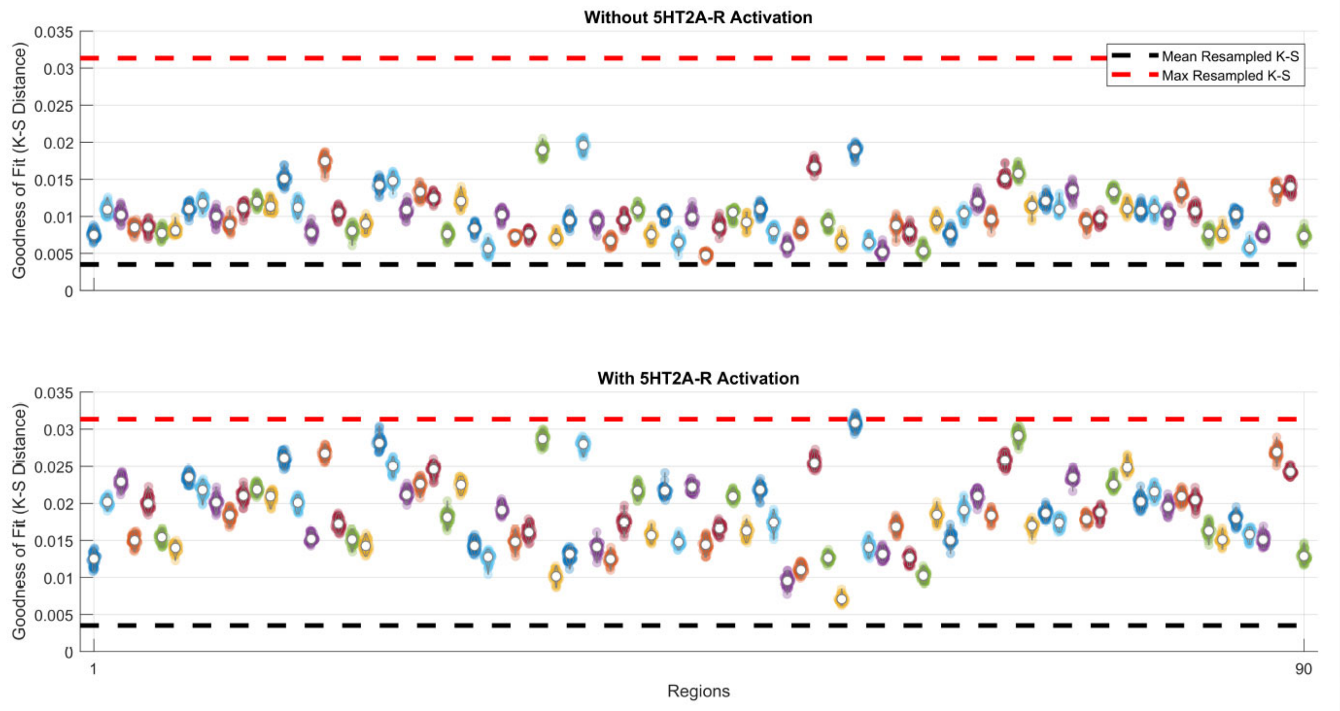


Supplementary Figure 4. Controls for receptor distribution vs Δh_n. Δh_n vs connectivity strength is plotted for 5HT2A-R, Uniform, 5HT4-R, and Random distribution of receptors (see text for details). The specific distribution of 5HT2A-R is critical both for the heterogeneity of Δh_n and for the average increase in local entropy. Circles are averages from 1000 independent simulations.

Supplementary Subsection 5. The probability distribution of excitatory firing rates can be well fitted by a Gamma distribution.

To check the goodness of fit (GOF) of Gamma distribution to the simulated excitatory firing rates of each region, we generated 10^6 simulation points for each region under both PLA and 5HT2A condition, then, a Gamma distribution was fitted and the Kolmogorov-Smirnov (K-S) distance between the firing rate distribution and 1000 random samples (same size) of the respective fitted Gamma distribution was computed. We summarise the Gamma GOF as the average K-S for each region under both conditions. To assess the significance of average GOF values, we generated an acceptance interval computing the K-S distance between 100 independent samples (same size) sampled from exactly the same Gamma distribution (re-sampled K-S). This procedure was repeated for different set of Gamma distribution parameters. If the average K-S distance of a given region falls below the maximum re-sampled K-S distance, we consider this region to be well fitted by the Gamma distribution.

Despite the decreased GOF under 5HT2A condition (compared to PLA) all regions fall within the acceptance interval under both conditions, enabling us to use the Gamma distribution parameters to estimate each region's Shannon's differential entropy.



Supplementary Figure 5. Goodness of fit of Gamma distribution to firing rates distribution are within confidence intervals. Distribution of K-S distance values for PLA (top) and 5HT2A-R (bottom) condition for each region are represented by violins, where white circle denotes average K-S. Black (red) dashed line represent the average (maximum) re-sampled K-S distance (see the text for details).

Supplementary Subsection 6. Brain Regions of the Automated Anatomical Labeling.

Supplementary Table 1. AAL regions and abreviations

AAL Abbreviation	Brain Regions
Precentral	Precental gyrus
Front Sup	Superior frontal gyrus, dorsolateral
Front Sup Orb	Superior frontal gyrus, orbital part
Front Mid	Middle frontal gyrus
Front Mid Orb	Middle frontal gyrus, orbital part
Front Inf Oper	Inferior frontal gyrus, opercular part
Front Inf Tri	Inferior frontal gyrus, triangular part
Front Inf Orb	Inferior frontal gyrus, orbital part
Rolandic Oper	Rolandic operculum
Supp Motor Ar	Supplementary motor area
Olfactory	Olfactory cortex
Frontal Sup Med	Superior frontal gyrus, medial
Frontal Mid Orb	Superior frontal gyrus, medial orbital
Rectus	Gyrus rectus
Insula	Insula
Cingulum Ant	Anterior cingulate and paracingulate gyri
Cingulum Mid	Median cingulate and paracingulate gyri
Cingulum Post	Posterior cingulate gyrus
Hippocampus	Hippocampus
ParaHippocamp	Parahippocampal gyrus
Amygdala	Amygdala
Calcarine	Calcarine fissure and surrounding cortex
Cuneus	Cuneus
Lingual	Lingual gyrus
Occipital Sup	Superior occipital gyrus
Occipital Mid	Middle occipital gyrus
Occipital Inf	Inferior occipital gyrus
Fusiform	Fusiform gyrus
Postcentral	Postcentral gyrus
Parietal Sup	Superior parietal gyrus
Parietal Inf	Inferior parietal, but supramarginal and angular gyri
SupraMarginal	Supramarginal gyrus
Angular	Angular gyrus
Precuneus	Precuneus
Paracentral Lobule	Paracentral lobule
Caudate	Caudate nucleus
Putamen	Lenticular nucleus, putamen
Pallidum	Lenticular nucleus, pallidum
Thalamus	Thalamus
Heschl	Heschl gyrus
Temporal Sup	Superior temporal gyrus
Temporal Pol Sup	Temporal pole: superior temporal gyrus
Temporal Mid	Middle temporal gyrus
Temporal Pol Mid	Temporal pole: middle temporal gyrus
Temporal Inf	Inferior temporal gyrus

Supplementary Subsection 7. Anatomical and Functional Grouping of Brain Regions.

Supplementary Table 2. Anatomical Grouping

Anatomical Group	AAL Regions
Cingulate	Cingulum Ant
	Cingulum Mid
	Cingulum Post
Frontal	Frontal Sup
	Front Sup Orb
	Front Mid
	Front Mid Orb

Salience (Sal)	Front Sup Orb
	Front Mid
	Front Mid Orb
	Front Inf Orb
	Supp Motor Ar
	Insula
	Cingulum Ant

Supplementary Subsection 8. Tractography

For the sake of completeness, in the following we describe in detail the methods used by Ref.[1] to obtain the human connectome. We clarify that we did not produce these connectome data sets, instead, we used data kindly provided by Gustavo Deco.

The structural connectivity between the 90 AAL regions was obtained from averaging across 16 healthy young adults (5 females, mean SD age: 24.75 2.54). The linear registration tool from the FSL toolbox (www.fmrib.ox.ac.uk/fsl, FMRIB, Oxford) was used to coregister the EPI image to the T1-weighted structural image. The T1-weighted image was co-registered to the T1 template of ICBM152 in MNI space. The resulting transformations were concatenated and inversed and further applied to warp the AAL template from MNI space to the EPI native space, where interpolation using nearest-neighbor method ensured that the discrete labeling values were preserved. Thus the brain parcellations were conducted in each individual's native space. The structural connectivity (SC) maps were generated for each participant using the dMRI data acquired. The two data sets acquired have different phase encoding to optimize signal in difficult regions. The construction of these structural connectivity maps consisted of a three-step process. First, the regions of the whole-brain network were defined using the AAL template as used in the functional MRI data. Second, the connections between nodes in the whole-brain network (i.e., edges) were estimated using probabilistic tractography. Third, data was averaged across participants.

The FSL diffusion toolbox (Fdt) was used to carry out the various processing stages of the diffusion MRI data using the default parameters of this imaging pre-processing pipeline on all participants. Following this preprocessing, we estimated the local probability distribution of fiber direction at each voxel. The probtrackx tool in Fdt was used to provide automatic estimation of crossing fibers within each voxel.

The connectivity probability from a seed voxel i to another voxel j was defined by the proportion of fibers passing through voxel i that reach voxel j using a sampling of 5000 streamlines per voxel. This was extended from the voxel level to the region level, i.e., in an AAL parcel consisting of n voxels, 5000x n fibers were sampled. The connectivity probability Pij from region i to region j is calculated as the number of sampled fibers in region i that connect the two regions divided by 5000 x n, where n is the number of voxels in region i. The SC matrix was thresholded at 0.1%, i.e., five streamlines.

For each brain region, the connectivity probability to each of the other 89 regions within the AAL was calculated. Due to the dependence of tractography on the seeding location, the probability from i to j is not necessarily equivalent to that from j to i. However, these two probabilities are highly correlated across the brain for all participants (the least Pearson $r = 0.70$, $p < 10^{-}50$). As directionality of connections cannot be determined based on diffusion MRI, the unidirectional connectivity probability Pij between regions i and j was defined by averaging these two connectivity probabilities. This unidirectional connectivity was considered as a measure of the structural connectivity between the two areas, with $Cij = Cji$. The regional connectivity probability was calculated using in-house Perl scripts. For both phase encoding directions, 90x90 symmetric weighted networks were constructed based on the AAL90 parcellation, and normalized by the number of voxels in each AAL region; thus representing the structural connectivity network organization of the brain.

A commentary on Disrupting posterior cingulate connectivity disconnects consciousness from the external environment *by Herbet, G., Lafargue, G., de Champfleur, N. M., Moritz-Gasser, S., le Bars, E., Bonnetblanc, F., et al. (2014). Neuropsychologia 56C, 239-244. doi: 10.1016/j.neuropsychologia.2014.01.020*

Reminiscent of Wilder Penfield's famous experiments, Neurologists in France have reported a remarkable case in which intraoperative electrical stimulations of the posterior cingulate cortex (PCC) in a conscious patient induced transient dreamlike states with vivid visual imagery (Herbet *et al*., 2014). The implicated circuitry and nature of the experiences evoked comparisons with findings from our own neuroimaging research with the hallucinogen and putative "oneirogen" (dream-inducer) psilocybin, strengthening what can be inferred about the importance of the PCC in mediating the quality of consciousness.

We were fascinated to read the case-report of a dreamlike experience evoked by direct electrical stimulation of the posterior cingulate cortex (PCC) in an epilepsy patient by Herbet *et al*. (2014). The PCC has attracted a lot of interest in recent years due to recognition of its high metabolic and vascular demand (Raichle *et al*., 2001) and importance as a cortical connector hub (Hagmann *et al*., 2008) and integration center (Leech *et al*., 2012). Perhaps due to its buffered location and rich vascular innervation, there is an absence of cases of focal PCC lesions (Leech and Sharp, 2014) and to our knowledge there are no reports on the effects of PCC stimulation in humans. There are a few case-reports of impaired spatial navigation and related symptoms of Balint's syndrome in patients with damage to the retrosplenial cortex (Leech and Sharp, 2014) but the stimulation site here was dorsal to the retrosplenial cortex, in white matter of the cingulum bundle, a major tract connecting the PCC with the medial prefrontal cortex (mPFC). This circuit constitutes the spine of the default-mode network (DMN), a system that has been associated with spontaneous cognition that is suspended or interrupted during periods of externally-directed attention (Raichle *et al*., 2001).

Upon reading Herbet *et al*.'s report, we were struck by similarities between the subjective reports given post-PCC stimulation and those we observed after controlled administration of the classic hallucinogen, psilocybin (Carhart-Harris *et al*., 2012; Muthukumaraswamy *et al*., 2013). As Herbet *et al*. discuss, stimulation of the PCC/cingulum bundle likely inhibited activity in this region and interrupted communication between the mPFC and PCC. Importantly, altered PCC activity (i.e., decreased blood flow and oscillatory power and mPFC-PCC functional connectivity) was the most conspicuous and reliable finding of our psilocybin imaging studies and volunteers reported experiencing a dreamlike state and vivid visual imagery (Carhart-Harris *et al*., 2012, 2014; Muthukumaraswamy *et al*., 2013). Moreover, sustained improvements in well-being (Griffiths *et al*., 2006) and lasting decreases in depressive symptoms have been reported post-psilocybin (Grob *et al*., 2011) and it was remarkable to read Herbet *et al.*'s patient describe an absence of rumination and "absolute happiness" for a sustained period after resection of the PCC. Is it possible that psilocybin produces a sustained alteration in PCC and/or DMN activity that could account for its putative therapeutic potential (Carhart-Harris *et al.*, 2014)? This is something we intend to test in a forthcoming trial of psilocybin as a treatment for major depression (Roiser and Rees, 2012).

Finally, the theoretical implications of Herbet *et al.*'s report are profound. The authors note that PCC cerebral blood flow is decreased in rapid eye movement (REM) sleep relative to waking (Braun *et al.*, 1997) and non-REM sleep (Maquet *et al.*, 1996). It has long been a matter of intrigue to us that LSD given just before sleep onset (Muzio *et al.*, 1966) or intravenously during sleep (Torda, 1968) markedly promotes REM sleep. The classic serotonergic hallucinogens LSD, psilocybin and dimethyltryptamine are known to produce vivid and complex imagery, especially with eyes-closed, that are often described as dreamlike (Grinspoon and Bakalar, 1979). Another common feature of the REM-sleep and hallucinogenic drug states is alterations in medial temporal lobe (MTLs) activity. For example, the MTLs are hyperactive in REM-sleep (Maquet *et al.*, 1996; Braun *et al.*, 1997; Miyauchi *et al.*, 2009) and show an increased amplitude in their signal fluctuations post-psilocybin (Carhart-Harris *et al.*, 2014) which correlates with reports of dreamlike phenomena (Figure 1). The MTLs are another area where electrical stimulation can produce vivid dreamlike visions of the sort reported by Herbet *et al.*'s patient (Vignal *et al.*, 2007). MTL stimulations producing dreamlike states have been found to induce a spreading activation from the stimulation site to the temporal and visual cortex (Barbeau *et al.*, 2005; Bartolomei *et al.*, 2012). However, the stimulations in the present case were in white matter and thus likely had an inhibitory rather than excitatory effect (Holtzheimer *et al.*, 2012).

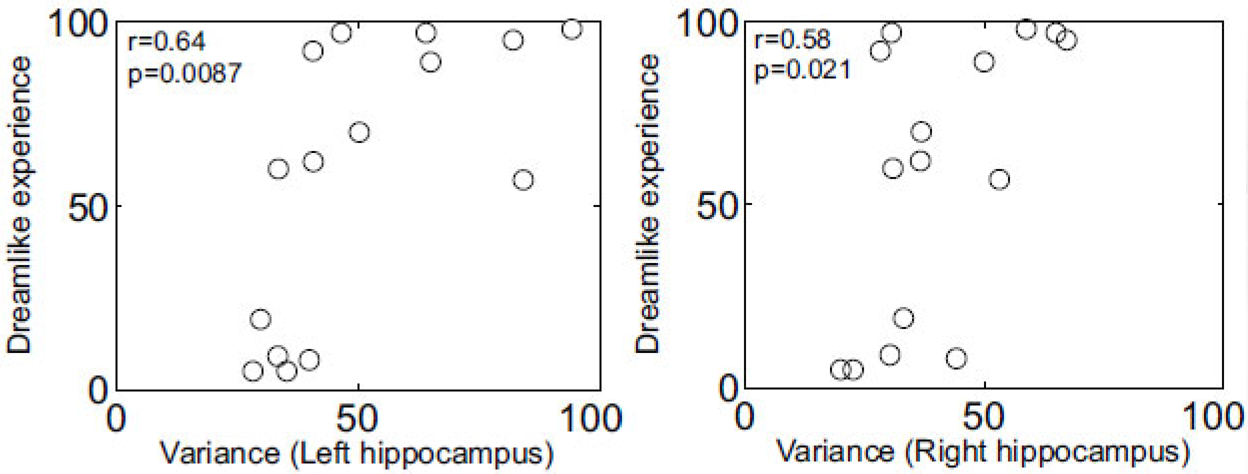

FIGURE 1 - Scatter plot of the increase in left and right hippocampal blood oxygen-level dependent signal variance/amplitude (after psilocybin infusion) vs. subjective ratings of the item: "the experience had a dreamlike quality." Both measures are expressed as a percentage increase from baseline. There were no changes in BOLD signal variance after placebo infusion ($n = 15$) (Carhart-Harris *et al.*, 2014).

So, how might disrupting DMN activity be the cause of dreamlike visions? One way to address this question is to look for clues from studies on REM-sleep and other dreamlike states. Firstly, it is worth noting that the MTLs are major subcortical nodes of the DMN (Supekar *et al.*, 2010) but under psilocybin, MTL-DMN coupling is decreased (Carhart-Harris *et al.*, 2014). Similarly, PCC activity is decreased in REM-sleep (Maquet *et al.*, 1996) and under psilocybin (Carhart-Harris *et al.*, 2014) but MTL activity is increased (Maquet *et al.*, 1996; Carhart-Harris *et al.*, 2014). Since MTL activity is coupled to phasic events in REM-sleep, including REMs (Bodizs *et al.*, 2001; Karashima *et al.*, 2007), the link between MTL activity and dreaming appears to be particularly intimate. Thus, disrupting DMN activity may have had a disinhibiting effect on MTL activity (Carhart-Harris *et al.*, 2014) and this may have been the cause of the ensuing dreamlike visions (Carhart-Harris, 2007; Carhart-Harris and Friston, 2010; Carhart-Harris *et al.*, 2014). Future neuroimaging work on dreaming and dreamlike states will help to inform these speculations.

In summary, we were struck by similarities between Herbet *et al.*'s findings with direct electrical stimulation of the PCC and those of our own with psilocybin and neuroimaging. Their case provides some causative support for the notion that the PCC is centrally involved in mediating the *quality* of consciousness (Carhart-Harris *et al.*, 2014), and more specifically, that inhibiting the PCC/disrupting DMN activity can induce dreamlike states. Moreover, we are intrigued by the possibility that drug and stimulation-induced dreamlike states are indeed truly dreamlike, i.e., in the neurophysiological sense as well as the phenomenological.

Abstract

Drugs that modulate serotonin (5-HT) synaptic concentrations impact neurogenesis and hippocampal (HPC)-dependent learning. The primary objective is to determine the extent to which psilocybin (PSOP) modulates neurogenesis and thereby affects acquisition and extinction of HPC-dependent trace fear conditioning. PSOP, the 5-HT_{2A} agonist 25I-NBMeO and the 5-$HT_{2A/C}$ antagonist ketanserin were administered via an acute *intraperitoneal* injection to mice. Trace fear conditioning was measured as the amount of time spent immobile in the presence of the conditioned stimulus (CS, auditory tone), trace (silent interval) and post-trace interval over 10 trials. Extinction was determined by the number of trials required to resume mobility during CS, trace and post-trace when the shock was not delivered. Neurogenesis was determined by unbiased counts of cells in the dentate gyrus of the HPC birth-dated with BrdU co-expressing a neuronal marker. Mice treated with a range of doses of PSOP acquired a robust conditioned fear response. Mice injected with low doses of PSOP extinguished cued fear conditioning significantly more rapidly than high-dose PSOP or saline-treated mice. Injection of PSOP, 25I-NBMeO or ketanserin resulted in significant dose-dependent decreases in number of newborn neurons in hippocampus. At the low doses of PSOP that enhanced extinction, neurogenesis was not decreased, but rather tended toward an increase. Extinction of "fear conditioning" may be mediated by actions of the drugs at sites other than hippocampus such as the amygdala, which is known to mediate the perception of fear. Another caveat is that PSOP is not purely selective for 5-HT_{2A} receptors. PSOP facilitates extinction of the classically conditioned fear response, and this, and similar agents, should be explored as potential treatments for post-traumatic stress disorder and related conditions.

Introduction

Psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine, PSOP) was first isolated from *Psilocybe mexicana*, a mushroom from Central America by Albert Hofmann in 1957 and soon after produced synthetically in 1958 (Hofmann *et al*. 1958a, b). PSOP is an indole hallucinogen with potential clinical applications in the treatment for anxiety disorders, obsessive-compulsive disorder, major depression and cluster headaches (Moreno *et al*. 2006; Grob *et al*. 2011; Young 2013). PSOP is dephosphorylated in the body and converted into the active metabolite psilocin (4-hydroxy- *N,N*-dimethyltryptamine) which exerts psychoactive effects by altering neurotransmission through serotonin (5-HT) receptors 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2A} and 5-HT_{2C}, but binds to 5-HT_{2A} receptors with high affinity (Ki = 6 nM) (McKenna *et al*. 1990; Passie *et al*. 2002). 5-HT_{2A} receptors are highly expressed throughout the hippocampus (HPC) in the dentate gyrus (DG), hilus, cornu ammonis (CA) 1 and CA3 and are colocalized on GABAergic neurons, pyramidal and granular cells (Luttgen *et al*. 2004; Morilak *et al*. 1993, 1994; Pompeiano *et al*. 1994; Shen and Andrade 1998; Cornea-Hebert *et al*. 1999). 5-HT_{2A} receptor down-regulation is thought to be an adaptive process triggered by chronic administration of selective 5-HT uptake inhibitors (SSRIs) (Eison and Mullins 1996).

Antidepressant medications which elevate 5-HT over prolonged periods such as SSRIs have been shown to enhance hippocampal neurogenesis (Malberg *et al*. 2000). Neurogenesis occurs throughout the life span in the adult brain, the subventricular zone (SVZ) and the subgranular zone (SGZ) in the DG (Altman 1962, 1969; Altman and Das 1965). The proliferation and survival of neural progenitors in the adult HPC can be influenced by a variety of stimuli including stress, age, drugs of abuse, physical activity and depression (Malberg *et al*. 2000; Van *et al*. 1999; Kempermann *et al*. 1998; Gould *et al*. 1992). The involvement of 5-HT in the regulation of neurogenesis may be mediated through different 5-HT receptor subtypes expressed on cells in the neurogenic microniche (Barnes and Sharp 1999).

Serotonin activates fifteen known receptors, many of which are expressed in the DG (Tecott *et al*. 1993; Vilaro *et al*. 1996; Djavadian *et al*. 1999; Clemett *et al*. 2000; Kinsey *et al*. 2001). Acute activation of the 5-HT_1 receptor has been shown to increase cell proliferation in the DG, whereas repeated inhibition of the receptor results in diminished neurogenesis (Klempin *et al*. 2010). Interestingly, both acute and repeated stimulation of the 5-HT_2 receptor attenuate proliferation and neuronal survival (Klempin *et al*. 2010). Studies investigating the effects of 5-HT_2 receptor subunits on proliferation and neurogenesis in the DG have found that acute activation of the 5-$HT_{2A/C}$ receptor via 2,5-dimethoxy-4-iodoamphetamine (DOI), the 5-HT_{2C} receptor agonist RO 600175 or the 5-HT_{2C} receptor antagonist SB-206553 had no effect on cell proliferation, whereas the 5-$HT_{2A/C}$ receptor antagonist ketanserin produced a 63 % decrease in BrdU incorporation (Banasr *et al*. 2004). Similarly, other investigators reported that acute ketanserin decreased proliferation, but chronic ketanserin increased proliferation in the DG (Jha *et al*. 2008). Additionally, no effect on proliferation was observed after DOI or lysergic acid diethylamide (LSD) was administered either acutely or once daily for seven consecutive days (chronic) (Jha *et al*. 2008). Administering LSD and PSOP by giving daily doses has been shown to produce rapid tolerance to the drug and results in a selective down-regulation of the 5-HT_{2A} receptor (Buckholtz *et al*. 1985, 1990).

The serotonergic system has been implicated in hippocampal (HPC)-dependent learning. Administration of SSRIs produces alterations in performance on learning tasks that require the HPC (Flood and Cherkin 1987; Huang *et al*. 2004). In a knockout (KO) mouse model, central 5-HT-deficient mice developed heightened contextual fear conditioning which was reversed by intracerebroventricular microinjection of 5-HT (Dai *et al*. 2008). An impairment in learning on the Morris water maze was observed in 5-HT_{1A} KO mice along with functional abnormalities in the HPC (Sarnyai *et al*. 2000). Activation of 5-HT_{1A} receptors in the medial septum alters encoding and consolidation in a HPC-dependent memory task (Koenig *et al*. 2008). In addition, LSD facilitated learning of a brightness discrimination reversal problem (King *et al*. 1972, 1974).

Evidence suggests that performance on HPC-dependent learning tasks is influenced by neurogenesis in the DG of the HPC (Van *et al*. 2002; Gould *et al*. 1999a, b; Nilsson *et al*. 1999; Shors *et al*. 2001, 2002). This was elegantly demonstrated by Shors *et al*. by treating animals with methylazoxymethanol acetate (MAM), an antimitotic agent which eradicates the progenitor cell population in the DG before testing mice on HPC-dependent and HPC-independent learning tasks (Shors *et al*. 2001, 2002). MAM-treated animals had significantly fewer BrdU+ cells in the SGZ but showed no impairment in the spatial navigation task (HPC-dependent) or delay eyeblink conditioning task (HPC-independent), demonstrating that the hippocampal progenitor cell population is not essential for these particular tasks (Shors *et al*. 2001, 2002). In contrast, MAM severely impaired performance on trace fear conditioning and trace eyeblink conditioning, providing evidence for the involvement of progenitor cells in the DG in trace classical conditioning.

The present study investigated the role of PSOP through the 5-HT_{2A} receptor on hippocampal neurogenesis and a HPC-dependent learning task, trace fear conditioning. The effects of single-dose injections of PSOP, the 5-HT_{2A} agonist 25I-NBMeO and the 5-$HT_{2A/C}$ antagonist ketanserin on the survival and phenotypic fate of progenitor cells in the DG were assessed using immunofluorescence techniques. The effects of single doses of PSOP on trace fear conditioning were chosen for this study because it has previously been demonstrated to be a HPC-dependent learning paradigm.

Materials and methods

Animals

C57BL/6J male mice (30-40 g) were housed in standard laboratory cages and left undisturbed for 1 week after arrival at the animal facility. All mice had ad libitum access to water and laboratory chow and were maintained in a temperature- and humidity-controlled room on a 12:12 light/dark cycle with light onset at 7:00 a.m. This study was carried out in strict accordance with the recommendations from the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The protocol was approved by the Institutional Animal Care and Use Committee at the University of South Florida (IAC UC #R3347).

Drugs

25I-NBMeO (4-iodo-2,5-dimethoxy-*N*-(2-methoxybenzyl) phenethylamine) was synthesized in the laboratory of Dr. David Nichols (Braden *et al*. 2006). PSOP was provided by Dr. Francisco Moreno from the University of Arizona. Ketanserin (+)-tartrate salt (#S006, St. Louis, MO) and 5-bromo-2′-deoxyuridine (#B5002, St. Louis, MO) were supplied by Sigma-Aldrich Inc.

General procedure

A total of 48 C57BL/6 mice received a single injection of 0.1 mg/kg PSOP ($n = 6$), 0.5 mg/kg PSOP ($n = 6$), 1.0 mg/ kg PSOP ($n = 6$), 0.1 mg/kg 25I-NBMeO ($n = 6$), 0.3 mg/ kg 25I-NBMeO ($n = 6$), 1.0 mg/kg 25I-NBMeO ($n = 6$), 1.0 mg/kg ketanserin ($n = 6$) or saline ($n = 6$). Mice received an intraperitoneal (i.p.) injection of 75 mg/kg BrdU once daily for 4 days following drug administration and were euthanized 2 weeks after drug injection. Mice were euthanized with nembutal and then transcardially perfused with 0.9 % saline followed by 4 % paraformaldehyde. Brains were stored in 4 % paraformaldehyde, transferred to 20 % sucrose solution, sectioned coronally using a cryostat (Leica, Germany) at 30 μM in a 1:6 series and stored in 24-well plates in cryoprotectant at -20 °C.

Trace fear conditioning

Mice (n = 9-10/condition) received an i.p. injection of PSOP (0.1, 0.5, 1.0 and 1.5 mg/kg), ketanserin (1.0 mg/ kg) or 0.9 % saline and 24 h later were habituated to the testing chamber for 30 min. The fear conditioning environment consisted of two chambers each placed inside a larger soundproof chamber. The 35.6 (W) × 38.1 (D) × 31.8 (H) cm freeze monitor box (San Diego Instruments, San Diego, CA) is a clear Plexiglas chamber with a removable lid which contains a metal grid floor (0.3-cm grids spaced 0.8 cm apart) through which a foot shock can be delivered. Photo-beam activity within the chamber recorded the vertical and horizontal movements of mice. Two minutes into the habituation period, a baseline (BL) measure of movement was recorded for 3 min and served as the habituation BL measure. Freeze monitor boxes were cleaned with quatricide between each mouse to prevent olfactory cues. Mice were returned to their home cage after habituation.

The next day mice were returned to the same freeze monitor chamber and underwent training to form CS-US associations. After a 2-min acclimation period, mice were exposed to 10 trials of trace fear conditioning, which is illustrated in Fig. 2. Each trial consisted of the CS (tone, 82 dB, 15 s) followed by a trace interval (30 s) and ended with the presentation of the US (shock, 0.5 s, 1 mA) delivered through the grid flooring. After each trial ended, there was a 210-s intertrial interval (ITI). Freeze monitor boxes were cleaned with quatricide between each mouse to prevent olfactory cues, and mice were returned to their home cage after training.

On day 3 of the task, retention and extinction of the conditioned fear response were assessed in three phases. First, mice were placed in the freeze monitor box for 5 min, and movement was recorded for the last 3 min and used to assess the measure of fear (immobility) associated with the training context. Mice were then returned to the home cage for 1 h. Second, the context was altered by replacing the grid floors with black Plexiglas flooring and adding a cotton ball with 1 ml vanilla essence inside the sound-attenuated chamber. Mice were placed inside the novel chamber, and after 2 min, movements were recorded for the next 3 min.

In the third phase, extinction of the conditioned fear response was determined by placing the animals in the freeze monitor boxes and running ten trials of CS presentation (auditory tone for 15 s) followed by a trace of silence for 30 s without delivery of the UCS (shock). As with the acquisition phase of the learning, a 210-s ITI separated each trial. The conditioned fear response was expressed as the percentage of time the mice were immobile during CS (tone; 15 s), during the trace interval (30 s) and for 30 s after the trace interval.

Immunofluorescence

For the double labeling of progenitor cells in the DG, free-floating sections were denatured using 2N HCl and neutralized in 0.15 M borate buffer and then washed in PBS. Tissue was blocked in PBS+ (PBS, 10 % normal goat serum, 1 % 100× Triton X, 10 % BSA) for 1 h at 4 °C and incubated for 48 h at 4 °C in an antibody cocktail of rat monoclonal anti-BrdU (AbD Serotec, Raleigh NC, #OBT0030G, 1:100) plus mouse anti-NeuN (Chemicon, 1:100) in PBS plus 2 % normal goat serum. Sections were washed in PBS and incubated in a secondary antibody cocktail of goat anti-rat IgG Alexa Fluor 594 (1:1,000, Invitrogen, Eugene OR) plus goat antimouse IgG Alexa Fluor 488 (1:400, Invitrogen) and coated with Vectashield mounting medium with DAPI (Invitrogen).

Quantitation

For the quantification of double-labeled cells using immunofluorescence, the number of BrdU+ - and BrdU/NeuN+ - labeled cells was estimated using every sixth section taken throughout the DG (every 180 microns). To avoid counting partial cells, a modification to the optical dissector method was used so that cells on the upper and lower planes were not counted. The number of BrdU+ cells counted in every sixth section was multiplied by six to get the total number of BrdU+ or BrdU/NeuN+ cells in the DG (Shors *et al*. 2002). Positive labeling was verified by confocal microscopy (Zeiss Model LSM510).

Design and statistical analyses

One-way analysis of variance (ANOVA) was used to evaluate the effects of PSOP, the 5-HT$_{2A}$ receptor agonist and an antagonist on hippocampal neurogenesis (proliferation and survival). Separate two-way repeated-measures ANOVA was used to evaluate the effect of Dose and Trial on each dependent variable in the trace fear conditioning task. Dependent measures recorded included percentage freezing during CS, during trace, after trace, during habituation baseline, during the context text and in response to the novel environment. When appropriate, post hoc analyses such as Bonferroni were used to isolate effects. All statistical analyses were determined significantly at the 0.05 alpha level.

Results

Effects of PSOP administration on trace fear conditioning

Acquisition of the conditioned fear response

Mice were placed in the freeze monitor box 24 h after injection of a single dose of PSOP (0.1, 1.0 and 1.5 mg/kg), ketanserin (1.0 mg/kg) or saline vehicle. Training consisted of a sequence of 10 trials of CS-UCS presentation. A single trial consisted of a 15-s auditory cue (CS) followed by a silent "trace" for 30 s terminating in a brief shock to the feet. The intertrial interval (ITI) was 210 s. After just a few trials, animals acquired the conditioned response, that is, freezing during presentation of the CS, trace and post-shock interval (Fig. 1). In trial 3, mice treated with low-dose PSOP (0.1 mg/kg) exhibited a trend toward less freezing (Fig. 1d). Two-way ANOVA showed a significant effect of Trial [$F(2,102) = 7.83$, $p < 0.0007$] with trials 2 and 3, eliciting significantly more freezing in response to the CS compared to trial one, but no significant effect of dose. Post hoc comparisons of each dose to vehicle, with Bonferroni correction, also did not reveal a significant difference between PSOP doses and saline. By trial 10, all mice froze for the same amount regardless of dose or drug treatment (Fig. 1e).

Contextual fear conditioning

Contextual fear conditioning was assessed by comparing percentage immobility in the freeze monitor box on habituation day to percentage immobility during the context test. There was no interaction between Dose and Trial [$F(5,90) = 0.95$, $p = 0.45$] and no effect of Dose during the habituation BL or context test [$F(5,90) = 1.15$, $p = 0.34$]. Notably, there was a significant effect of Trial [$F(1,90) = 105.85$, $p < 0.0001$], indicating that mice spent significantly more time freezing after the CS-US pairings during the context test compared to habituation baseline. These data show that all mice learned to fear the context in which they received the CS-US pairings (Fig. 2a, b).

Extinction of the conditioned fear response

A measure of the strength or durability of the conditioned fear response is the number of trials required to extinguish the conditioned response. This was determined by running a set of 10 extinction trials during which the CS and trace were not followed by shock. Two-way repeated-measures ANOVA of freezing after the trace interval revealed a significant interaction between Dose and Trial [$F(20,216) = 2.68$, $p < 0.0002$]. Mice that received low doses of PSOP (0.1 and 0.5 mg/kg) responded robustly to the CS and trace interval as well as to immediate post-trace interval of 30 s by freezing significantly greater than mice treated with vehicle in the very first extinction trial, indicating they "remembered" the link between the CS and the shock (Figs. 2c, 3c). However, by trial 3, the mice treated with low-dose PSOP no longer froze in the absence of the UCS, but adapted quickly to the new condition in which the CS and trace did not culminate in shock (Fig. 2e). Such rapid extinction of the fear response was not observed in mice treated with higher PSOP doses or with ketanserin. Mice that received higher doses of PSOP eventually decreased freezing, so that by trial 10 they no longer exhibited a fear response (Fig. 2f). Ketanserin treatment also produced a robust fear response through trial 3, but as with all mice treated with either PSOP or ketanserin, the fear response was significantly decreased compared to control by trial 10. These results indicate that low-dose PSOP facilitates extinction of the fear response in a hippocampal-dependent trace conditioning paradigm.

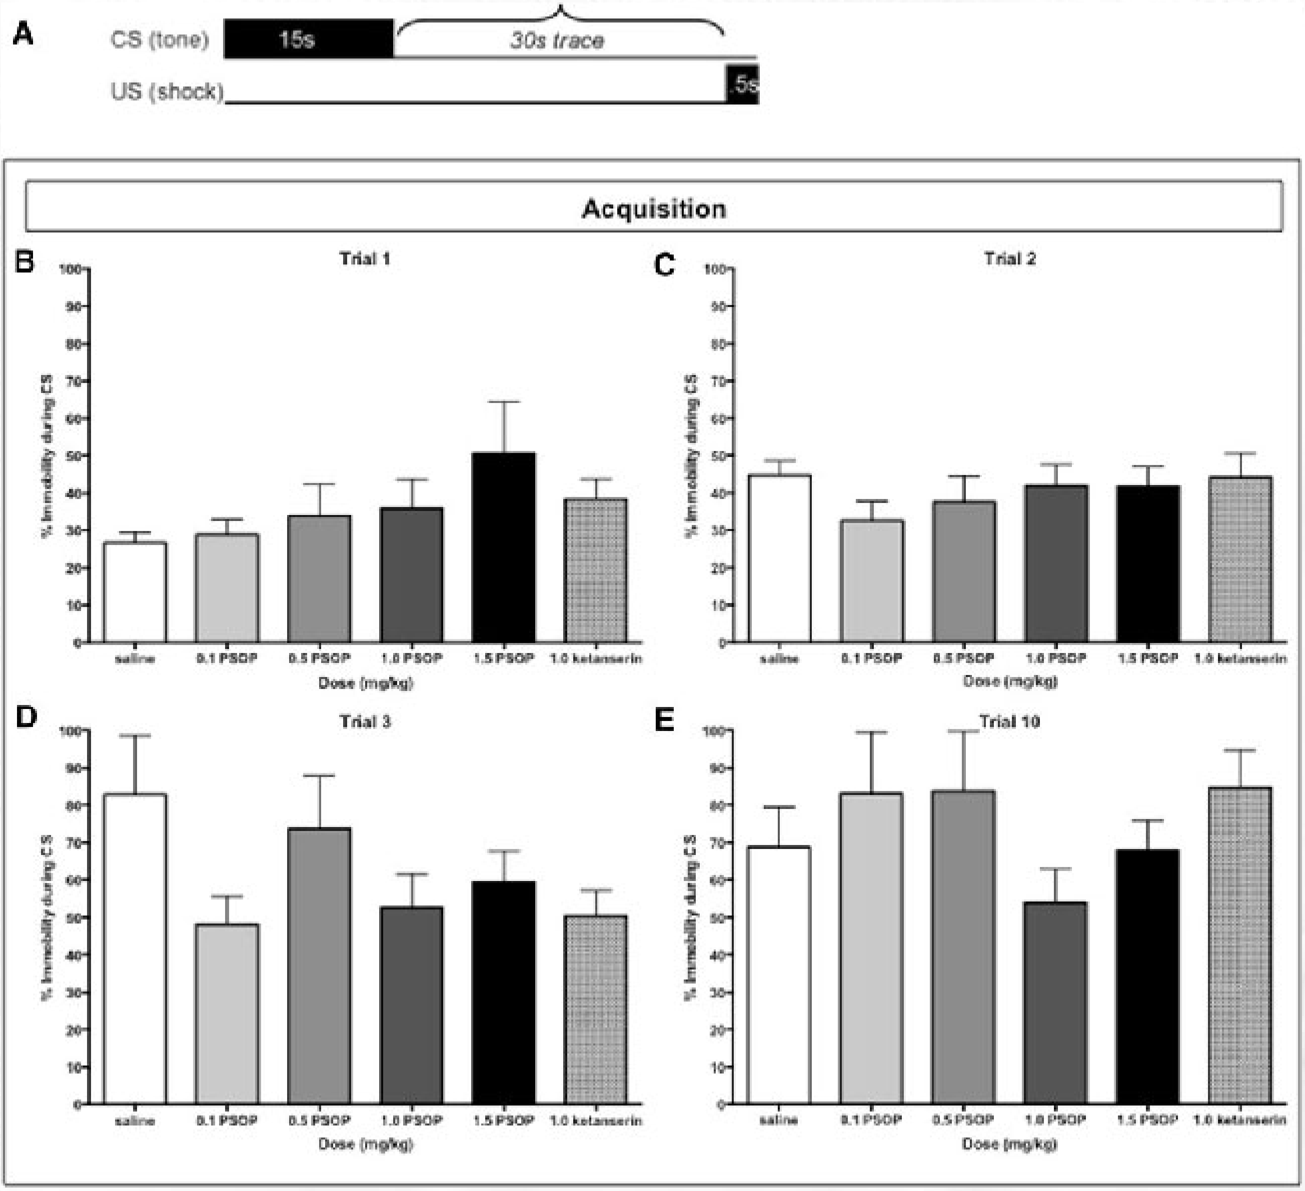

Fig. 1 Effects of psilocybin on acquisition of trace fear conditioning. **a** Schematic representation of the trace fear conditioning paradigm. Trace fear conditioning is a HPC-dependent task in which the presentation of the conditioned stimulus (CS, tone) is separated in time by a trace interval to the unconditioned stimulus (US, shock). **b-e** Percentage immobility during the CS is expressed on the *Y* axis and dose on the *X* axis. After trial 2 (**c**) animals acquired the conditioned response, freezing 34-45 % of the time during presentation of the CS. A quantitatively similar freezing response was observed during the trace and 30 s after the trace (data not shown). By trial 10 (**d**) all mice froze 55-80 % of the CS time interval regardless of drug dose. Two-way ANOVA showed a significant effect of Trial [$F(2,102) = 7.83$, $p < 0.0007$] with trials 2 and 3 eliciting significantly more freezing in response to the CS compared to trial 1 and dose [$F(5,51) = 4.96$, $p < 0.0009$]

Effects of PSOP, 25I-NBMeO and ketanserin in vivo on cell survival and neurogenesis in the hippocampus

To investigate the effects of a single dose of PSOP, the 5-HT$_{2A}$ receptor agonist 25I-NBMeO or antagonist ketanserin on cell survival and neurogenesis, mice (n = 6-7 per condition) were injected with PSOP (0.1, 0.5 or 1.0 mg/kg), 25I-NBMeO (0.1, 0.3 or 1.0 mg/kg), ketanserin (1.0 mg/kg) or 0.9 % saline solution followed by injections of the cellular birth-date marker BrdU (75 mg/kg) once daily for 4 days after drug administration. Animals were euthanized 2 weeks after drug injection. PSOP treatment produced a dose-dependent decrease in the number of surviving BrdU+ cells (Fig. 3). ANOVA showed a significant effect of dose on birth-dated cell survival, and post hoc comparison between doses and vehicle revealed a statistically significant decrease in cell survival following high doses of PSOP but not following the low doses of 0.1 and 0.5 mg/ kg (Fig. 3a). The phenotypic fate of BrdU-birth-dated cells was determined by immunofluorescent double labeling of BrdU+ and NeuN+ cells. There was a biphasic response of PSOP on neurogenesis, with the lowest dose (0.1 mg/kg) increasing number of BrdU/NeuN+ cells and the high dose (1 mg/kg) decreasing number of new neurons (Fig.

3b). One-way ANOVA revealed a highly significant effect of PSOP dose on the number of double-labeled neurons in the DG. Despite the trend toward stimulation of neurogenesis by 0.1 mg/kg PSOP, post hoc comparison of PSOP doses to vehicle did not reach statistical significance, but the depression of neurogenesis by the high dose of PSOP reached statistical significance. Ketanserin, like high-dose PSOP, also significantly decreased neurogenesis (number of BrdU/NeuN+ cells) compared to saline.

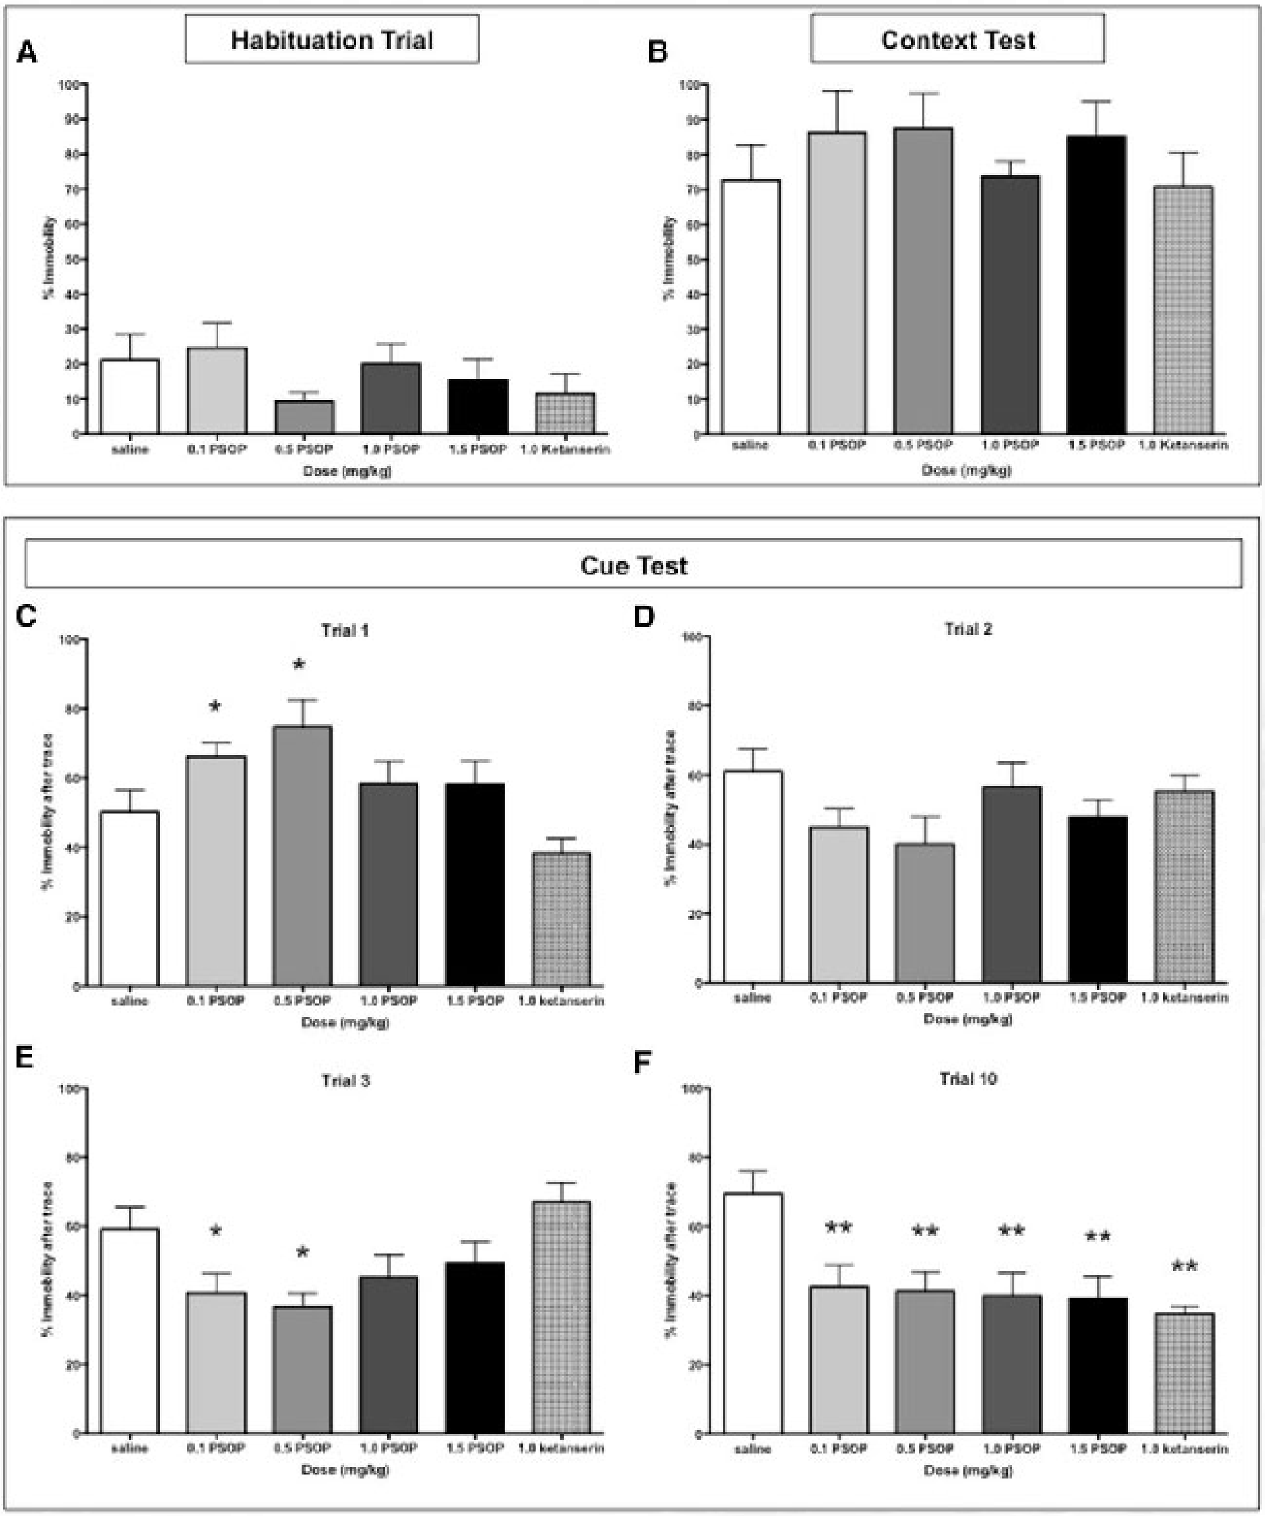

Fig. 2 Contextual fear conditioning and extinction. **a** Percentage immobility expressed during exposure to the freeze monitor box during habituation and b during the context test. All mice expressed contextual fear conditioning as indicated by a significant increase in percentage immobility during the context test ($p < 0.05$). **c-f** Cue test (presentation of CS and trace without shock; extinction protocol). *Y* axis shows percentage of time mice were immobile during the 30-s interval after the shock would have been delivered. Two-way repeated-measures ANOVA of freezing after the trace interval revealed a significant interaction between Dose and Trial [$F(20,216) = 2.68$, $p < 0.0002$]. **c** Mice treated with low-dose PSOP exhibited significant freezing on trial 1 of the extinction protocol. **d, e** By trials 2 and 3, low-dose-treated mice exhibited significantly less immobility. Control mice demonstrated robust fear conditioning throughout the entire test, whereas mice treated with PSOP or ketanserin froze significantly less by trial 10, indicating rapid extinction of the fear response. *Indicates a significant difference from ketanserin, **indicates a significant difference from saline.

Injections of 25I-NBMeO (0.1, 0.3 and 1 mg/kg) or of the antagonist ketanserin resulted in a significant decrease in the number of surviving BrdU+ cells and BrdU/NeuN+ neurons in hippocampus compared to saline injections (Fig. 3c, d). Unlike the PSOP injections, low doses of 25I-NBMeO did not produce a trend toward increased neurogenesis.

Discussion

The present investigation demonstrates that PSOP produces alterations in hippocampal neurogenesis and in a HPC-dependent learning paradigm of cue-associated fear conditioning. To evaluate the effects of PSOP on HPC-dependent learning, an acute treatment of PSOP or ketanserin was administered prior to trace fear conditioning. During the acquisition of the conditioned response, there was a striking increase in the amount of time spent freezing during the presentation of the CS and during the trace period and immediate post-trace interval from trial 1 to trial 3. These data demonstrate that the association between the CS and US promoted freezing in anticipation of the shock as well as during the period after the shock. Notably, the acquisition of the conditioned response was not impaired by acute administration of PSOP or ketanserin.

Regardless of the PSOP dose, mice displayed similar locomotor activity levels in the freeze monitor box during the habituation baseline exposure and during re-exposure to the same environment during the contextual fear conditioning test. As expected, mice froze substantially more during re-exposure to the same context after CS-US associations were formed compared to the habituation baseline, indicating that mice formed contextual fear conditioning regardless of their drug exposure. It is well known that contextual fear conditioning is a HPC-dependent learning task (Hirsh 1974; Kim and Fanselow 1992; McNish *et al*. 1997; Frohardt *et al*. 1999; Esclassan *et al*. 2009). The serotonergic system has been implicated in performance on the contextual fear conditioning task (Dai *et al*. 2008), and hippocampal neurogenesis is required for the expression of fear memory (Shors *et al*. 2001, 2002). The present investigation found that interaction with the 5-HT_{2A} receptor does not impair contextual fear conditioning since no differences were observed between controls and mice treated with PSOP or ketanserin.

Unlike the acquisition of the conditioned fear response, where drug had no significant effect on learning the association between CS, trace and shock (UCS), the extinction of the conditioned response was accelerated in mice treated with low doses of PSOP. This rapid reversal of fear conditioning was only observed with low-dose PSOP treatment and was not present with higher doses or with ketanserin. Thus, PSOP treatment does not alter acquisition of a conditioned fear response nor in remembering the link between the CS and UCs (contextual test), but low-dose PSOP facilitates extinction by disassociating the link between the CS, trace and the UCS (shock). Given that low doses of PSOP accelerated fear extinction, it is interesting to consider whether PSOP is blunting the emotional component of the fear memory which leads to rapid extinction. We observed that all mice freeze in response to each presentation of the shock during training and assume that for all mice regardless of the treatment, fear is evoked. In human studies, low doses of PSOP produce no differences in general well-being, emotional excitability, anxiety-depressiveness, plasma cortisol levels, heart rate, body temperature and blood pressure (Hasler *et al*. 2004). Taken together, we believe that the PSOP facilitation of fear extinction is not likely due to blunted emotion but instead caused by diminished neurogenesis and alterations in hippocampal neurotransmission.

The molecular basis for creating the links between CS and UCS in the trace conditioning paradigm is not completely understood. Clearly, synaptic plasticity in the HPC is critical for the acquisition of new associations (learning) and recall of those associations (memory). Brain-derived neurotrophic factor (BDNF) has been implicated in synaptic plasticity and memory processing (Kang *et al*. 1997; Pang *et al*. 2004; Tyler *et al*. 2002) through the modulation of synapse formation and dendritic spine growth in the HPC (Bamji *et al*. 2006; Tyler and Pozzo-Miller 2001, 2003). Chronic administration of 5-HT agonists (including SSRIs) upregulates BDNF mRNA expression in the HPC (Nibuya *et al*. 1995, 1996). Evidence suggests that the 5-HT_{2A} receptor is involved in the regulation of BDNF in the HPC (Vaidya *et al*. 1997). Specifically, DOI, a 5-$HT_{2A/C}$ receptor agonist, decreased BDNF mRNA expression in the granule cell layer of the DG, but not in the CA subfields of the HPC. Interestingly, the decrease in BDNF mRNA expression was blocked by the 5-HT_{2A} receptor antagonist, but not the 5-HT_{2C} receptor antagonist, implicating the 5-HT_{2A} receptor in the regulation of BDNF expression (Vaidya *et al*. 1997). The process of forgetting or breaking synaptic links in HPC is even less understood. One possible explanation for the findings presented here is that single low doses of PSOP acting via the 5-HT_{2A} receptors on HPC neurons inhibit BDNF expression and thereby decrease synaptic growth and neurogenesis.

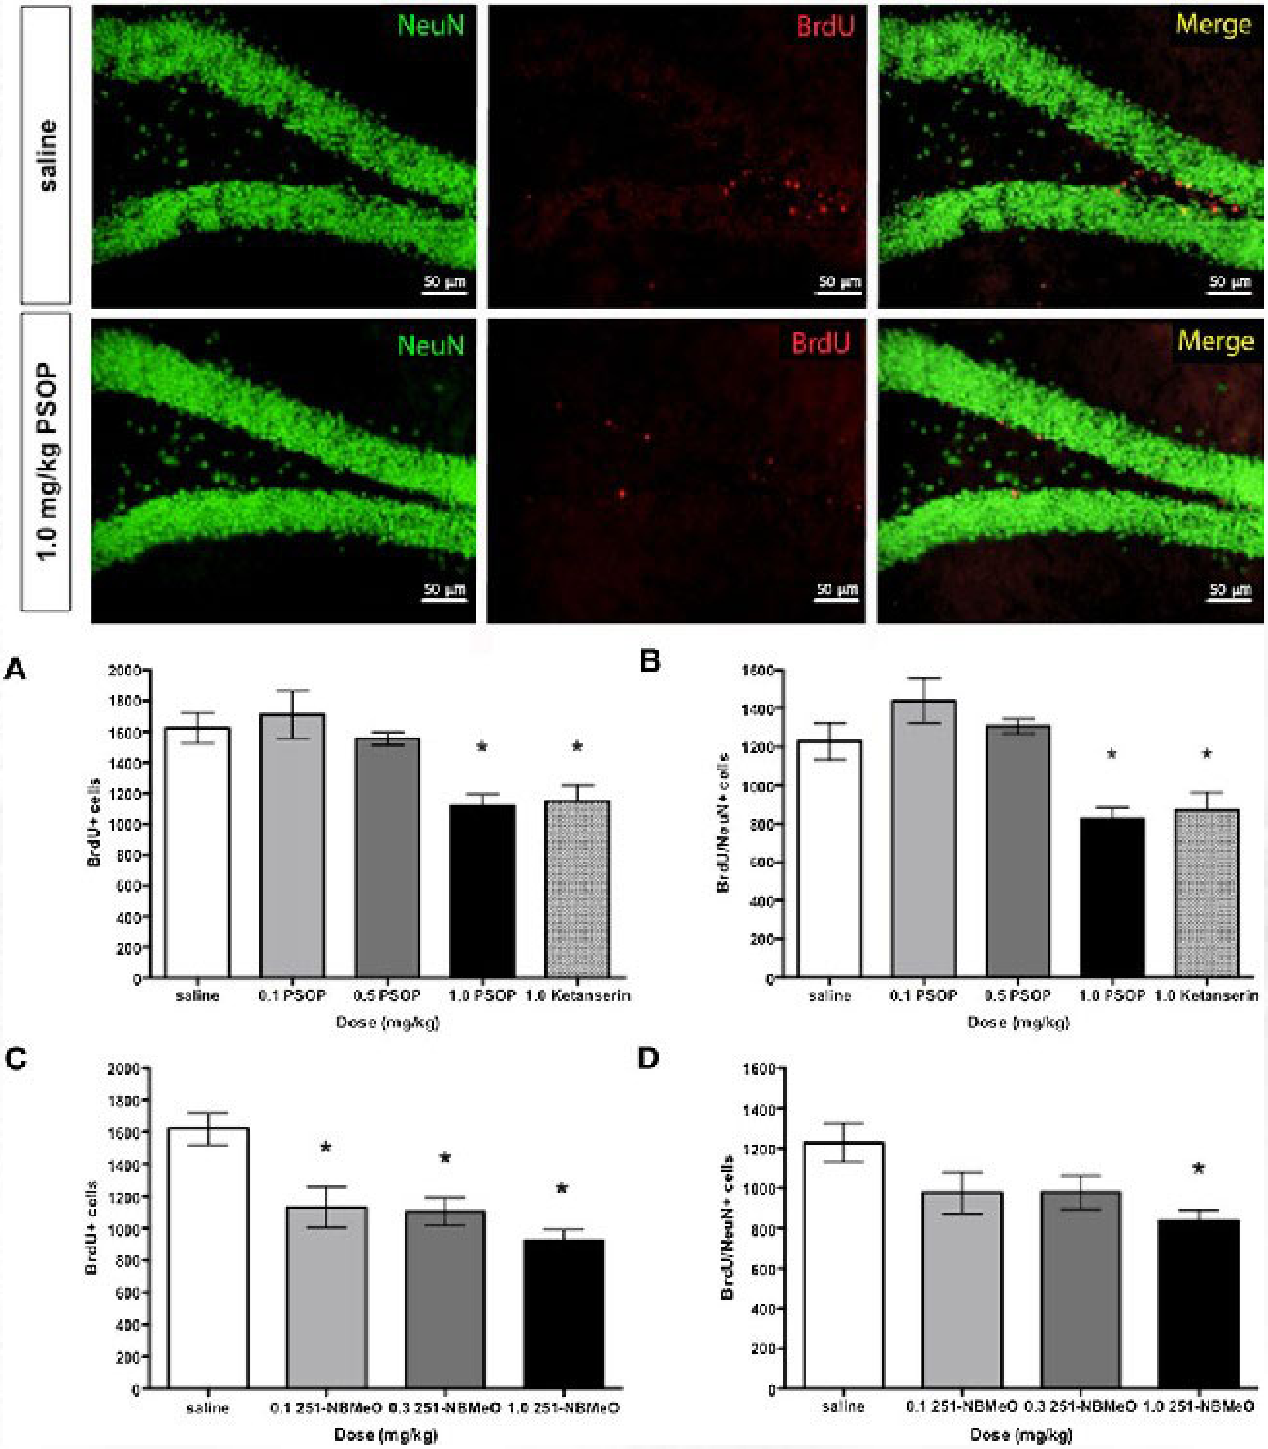

Fig. 3 Effect of acute 5-HT_{2A} receptor stimulation on hippocampal neurogenesis. Representative photomicrographs of NeuN+ cells (*left*), BrdU+ cells (*center*) and NeuN/BrdU+ cells (*right*) in the dentate gyrus from saline (*top*)- and 1.0 mg/kg PSOP (*bottom*)-treated mice, scale 50 µM. Mice (n = 6 per condition) were injected with **a, b** saline, PSOP (0.1, 0.5 or 1.0 mg/kg) or 1.0 mg/kg ketanserin **c, d** saline or 25I-NBMeO (0.1, 0.3 or 1.0 mg/kg) and then received 75 mg/kg BrdU once daily for 4 days after drug administration, followed by euthanasia 2 weeks after drug injection. **a, c** The total number of BrdU+ cells in the DG was significantly diminished after a single injection of 1.0 mg/kg PSOP, 25I-NBMeO or ketanserin ($p < 0.05$). **b, d** Acute administration of 1.0 mg/kg PSOP, 1.0 mg/kg of 25I-NBMeO and ketanserin significantly diminished the number of BrdU/NeuN+ cells compared to saline ($p <$ 0.05). These data suggest acute administration of 5-HT_{2A} receptor decreases progenitor cell survival (and/or proliferation) and attenuates the generation of new neurons in the HPC. *Indicates a significant difference from saline.

The data reported demonstrate that the administration of PSOP produced a biphasic response in hippocampal neurogenesis; a low dose (0.1 mg/kg) resulted in a trend toward increased neurogenesis, whereas the high dose of PSOP significantly decreased the formation of new neurons measured 2 weeks after drug exposure. In addition, all doses of the potent 5-HT_{2A} receptor agonist 25I-NBMeO and the 5-$HT_{2A/C}$ receptor antagonist ketanserin decreased hippocampal neurogenesis. A range of doses of ketanserin (1-5 mg/kg) administered within 4 h of killing has been reported to decrease the number of BrdU+ cells in the DG, indicating a reduction in cell proliferation (Banasr *et al*. 2004; Jha *et al*. 2008). The present study extends these findings by demonstrating that single doses of ketanserin decreased the number of BrdU+ and BrdU/NeuN+ cells 2 weeks after drug administration, indicating a reduction in both progenitor cell survival and formation of new neurons after exposure to a single dose of the 5-HT$_{2A/C}$ antagonist.

Using positron emission tomography (PET), Vollenweider *et al*. established that PSOP-induced schizophrenia, like psychosis, in humans is completely blocked by the 5-HT$_{2A}$ antagonist ketanserin, demonstrating that PSOP produces psychotropic effects mainly via 5-HT$_{2A}$ receptor activation (Vollenweider *et al*. 1998). However, PSOP administration decreases [^{11}C]raclopride receptor binding potential in the basal ganglia, which is indicative of increased DA levels (Vollenweider *et al*. 1999). Additionally, the D2 antagonist haloperidol attenuates the psychotomimetic effects of PSOP, clearly demonstrating that the DA system is involved in PSOP-induced psychotomimesis (Vollenweider *et al*. 1999). Interestingly, increases in DA disrupt fear extinction (Willick and Kokkinidis 1995; Borowski and Kokkinidis 1998); therefore, it is plausible that DA may contribute to PSOP facilitating the extinction of the fear response. Morrow and colleagues demonstrated that DAergic neurons which project to the medial prefrontal cortex (PFC) are critical in fear extinction and reduced rates of extinction are observed after 6-hydroxydopamine lesions to the PFC reduced DA levels to 13 % of control (Morrow *et al*. 1999). Furthermore, the activation of 5-HT$_{2A}$ receptors in the medial PFC increases extracellular glutamate levels (Aghajanian and Marek 1999), thereby affecting subcortical neurotransmission and increasing the activity of DA neurons in the ventral tegmental area (VTA), resulting in increased DA transmission in mesocortical and mesostriatal regions (Vazquez-Borsetti *et al*. 2009). Since drugs that increase DA bioavailability are involved in fear extinction, it is plausible that PSOP is facilitating fear extinction through an interaction between 5-HT and DA neurotransmitter systems in PFC, amygdala and HPC.

To summarize, the data reported in the present investigation demonstrate that PSOP at low doses facilitates extinction of a HPC-dependent classically conditioned fear response. Low dose of PSOP was also associated with a trend toward an increase, or no change, in hippocampal neurogenesis compared to vehicle treatment. In contrast, higher doses of PSOP (or of the 5-HT$_{2A/C}$ antagonist ketanserin) significantly depressed neurogenesis, and these doses had no impact on extinction of the conditioned fear response. Although previous studies have reported that ablation of hippocampal neurogenesis with a potent chemotherapeutic agent impaired acquisition of HPC-dependent fear conditioning (Shors *et al*. 2001, 2002), the present study did not reveal impaired acquisition of the trace fear conditioning response, likely due to modest inhibition of neurogenesis with the range of PSOP doses used. Importantly, studies of the effects of ablation of hippocampal neurogenesis focused on acquisition of the response and did not address extinction of a previously learned conditioned fear response as was done here. It is possible that the effect of low-dose PSOP on hippocampal neurogenesis, which was minimal, may not be the critical mechanism for forgetting or erasing the link between the noxious stimulus and the conditioned stimulus. PSOP clearly interacts with 5-HT$_{2A}$ receptors in other regions of brain known to mediate the emotion of fear such as amygdala (Ledoux 2003). However, one cannot invoke reduction in the fear emotion by PSOP because the acquisition of the conditioned fear response was not affected by PSOP administration at any dose. A final caveat is that PSOP is not a pure 5-HT$_{2A}$ agonist and may interact with other 5-HT receptor subtypes. In conclusion, low-dose PSOP which acts primarily on the 5-HT$_{2A}$ receptor facilitates extinction of a conditioned fear response and raises the possibility of targeting the 5-HT$_{2A}$ receptor to treat conditions where a previously neutral set of stimuli are associated with noxious, or life-threatening events, such as post-traumatic stress disorder.

Acknowledgments

This work was supported by the Helen Ellis Research Endowment (J.S.R.). Thanks to David Nichols Ph.D. for donating the selective 5-HT$_{2A}$ agonist 25I-NBMeO and Dr. Francisco Moreno from University of Arizona and Rick Doblin Ph.D. of the Multidisciplinary Association for Psychedelic Studies (MAPS) for donating the PSOP.

First and foremost thank you to Dr Kirstein and Dr Sanchez-Ramos for their complete support during my graduate studies. Dr Kirstein, you fought for me from the beginning and I am so grateful because I know none of this would have been possible without your advice and support. Dr Sanchez, you have taught me to think about the brain in a holistic way and with your passion for knowledge I learned that neuroscience is more than just a career, it is a way of life. Dr Paula Bickford, you are one of the most generous people I know, thank you for support and guidance and blessing me in so many ways. To Dr Brannick, Dr Cimino and Dr Shimizu, thank you for taking the time to serve on my committee and for your thoughtful consideration of my projects. I would also like to thank Dr Naomi Yavneh for chairing my defense.

On a personal level I am so grateful to have had the support of my family. To my Grandma, Nana, Mum, Dad, Pam, Steve, Jodi and Joanie you have all supported me in ways only family can and hope that I can do the same for you. To Anne, you have always been a role model to me with beauty, smarts, and positivity and I am so lucky to have you in my life. To Danielito, you opened my eyes and held my hand, ahora vamos!

Abstract

Aberrations in brain serotonin (5-HT) neurotransmission have been implicated in psychiatric disorders including anxiety, depression and deficits in learning and memory. Many of these disorders are treated with drugs which promote the availability of 5-HT in the synapse. Selective serotonin uptake inhibitors (SSRIs) are known to stimulate the production of new neurons in the hippocampus (HPC) by increasing synaptic concentration of serotonin (5-HT). However, it is not clear which of the 5-HT receptors are involved in behavioral improvements and enhanced neurogenesis. The current study aimed to investigate the effects of $5HT_{2A}$ agonists psilocybin and 251-NBMeO and the $5HT_{2A/C}$ antagonist ketanserin on neurogenesis and hippocampal-dependent learning. Agonists and an antagonist to the $5\text{-}HT_{2A}$ receptor produced alterations in hippocampal neurogenesis and trace fear conditioning. Future studies should examine the temporal effects of acute and chronic psilocybin administration on hippocampal-dependent learning and neurogenesis.

Chapter One

Introduction

The idea of new neurons forming in the adult central nervous system (CNS) is a relatively new one. In the 1960's Joseph Altman published the first evidence of neurogenesis, or the birth of new neurons in the adult mammalian brain (Altman, 1962; Altman, 1963; Altman & Das, 1965). Utilizing the tritiated thymidine method (Sidman *et al.*, 1959; Messier *et al.*, 1958; Messier & Leblond, 1960) Joseph Altman was able to demonstrate that the subventricular zone (SVZ) of the lateral ventricles and the dentate gyrus (DG) of the hippocampus (HPC) produce new neurons throughout the lifespan (Altman, 1962; Altman & Das, 1965; Altman, 1969). For years following Altman's discovery scientists acknowledged the possibility of the generation of new glial cells in the adult brain but rejected the concept of new born neurons. With the advent of new technologies such as the bromodeoxyuridine (BrdU) method of birth dating cells and double labeling using immunofluorescence, adult neurogenesis has been identified in many mammalian species including mice (Kempermann *et al.*, 1998), rats (Kaplan & Hinds, 1977), hamsters (Huang *et al.*, 1998), tree shrews (Gould *et al.*, 1997), nonhuman primates (Gould *et al.*, 1999b; Bernier *et al.*, 2002) and humans (Eriksson *et al.*, 1998). Peter Eriksson's discovery of new neurons in the human HPC changed the perception of neurogenesis in the scientific community so now the fact that new neurons are produced in the adult brain is firmly established.

The Anatomy of Hippocampal Neurogenesis

The HPC is divided into four areas: DG (also called area dentate, or fascia dentata), cornu ammonis (CA, further divided into CA1, CA2, CA3 and CA4), the presubiculum and the subiculum. This anatomical description of the HPC has been confirmed by both gene expression and fiber connections. The DG and areas CA form a trisynaptic circuitry within the HPC (see Figure 1.1). Neurons in the entorhinal cortex (EC) project to dendrites of the granule cells in the DG forming the perforant pathway. The granule cells extend their axons (Ramon, 1952) to pyramidal neurons in area CA3, forming the mossy fiber tract (Ribak *et al.*, 1985). CA3 pyramidal neurons project to the contralateral (via associational commissural pathway) and the ipsilateral CA1 region forming the Shaffer collateral pathway. Pyramidal neurons in CA1 extend axons to the subiculum and from the subiculum back to EC (for detailed descriptions of hippocampal circuitry see (Witter, 1993)).

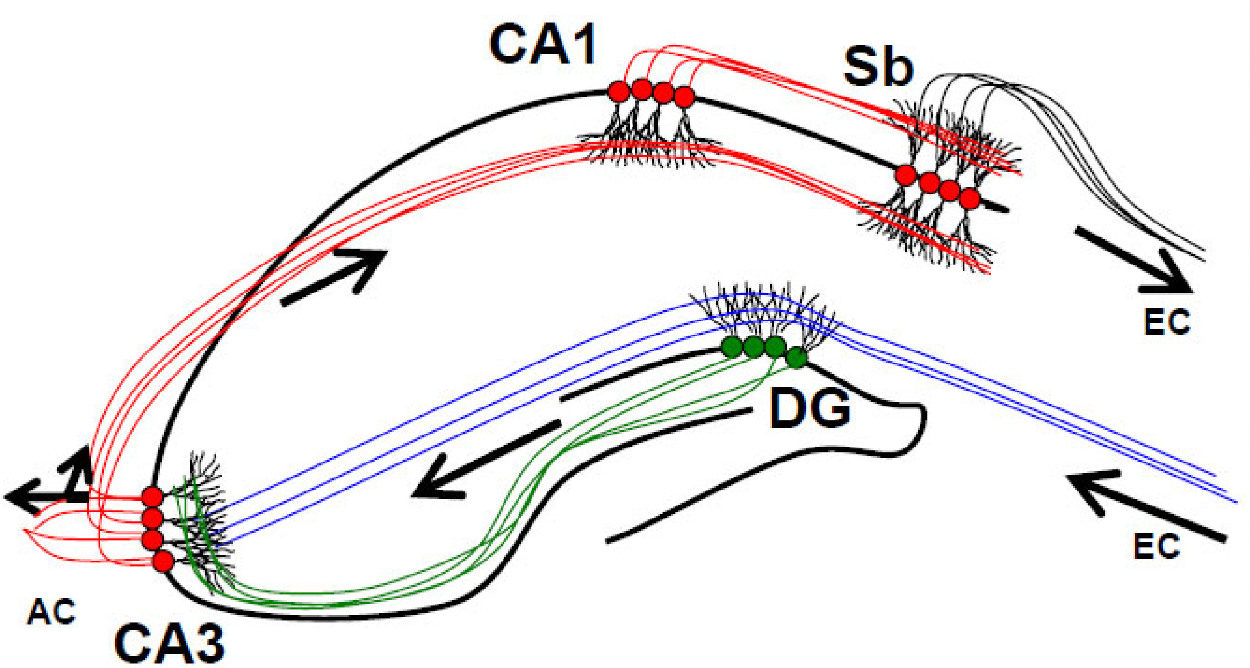

Figure 1.1. Anatomy of the Hippocampus. The HPC forms a trisynaptic pathway with inputs from the Entorhinal Cortex (EC) that projects to the Dentate Gyrus (DG) and CA3 pyramidal neurons via the perforant pathway. Granule cells in the DG project to CA3 via the mossy fiber pathway. Pyramidal neurons in CA3 project to both the contralateral (associational commissural pathway) and the ipsilateral CA1 region via the Schaffer Collateral Pathway. CA1 pyramidal neurons send their axons to the Subiculum (Sb) which in turn projects out of the HPC back to the EC.

In normal physiological conditions, neurogenesis that occurs in the HPC is found only in the DG and results in the generation of new granule cells. Within the DG, progenitor cells reside in a narrow band between the DG and the hilus (also called CA4 or plexiform layer) called the subgranular zone (SGZ) which is approximately 2-3 cells thick (20-25 µM) (see Figure 1.2). Neural progenitor cells (1) divide and form clusters of proliferating cells (2). Proliferating cells exit from the cell cycle and begin to differentiate into immature neurons (3). The immature granule cell forms sodium currents, extends dendrites and an axon to make connections with other cells and form synapses to become a mature neuron (4). The SGZ contains many cell types including astrocytes (Seri *et al.*, 2001; Filippov *et al.*, 2003; Fukuda *et al.*, 2003), several types of glial and neuronal progenitor cells (Filippov *et al.*, 2003; Fukuda *et al.*, 2003; Kronenberg *et al.*, 2003; Seri *et al.*, 2004) and neurons in all stages of differentiation and maturation (Brandt *et al.*, 2003; Ambrogini *et al.*, 2004).

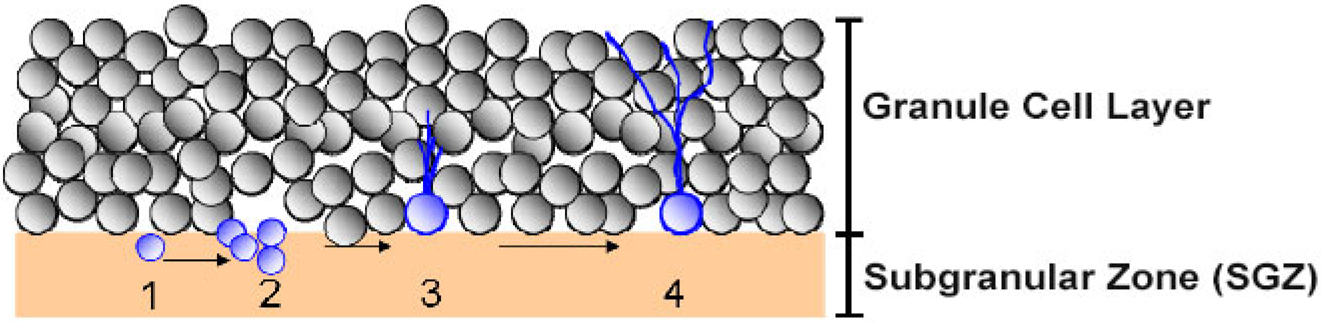

Figure 1.2. Neurogenesis in the Dentate Gyrus of the Hippocampus. Neural stem cells exist the SGZ of the DG, these cells then divide, differentiate and mature into their phenotypic fate. Neural progenitor cells (1) divide and form clusters of proliferating cells (2). Proliferating cells exit from the cell cycle and begin to differentiate into immature neurons (3). The immature granule cell forms sodium currents, dendrites and extends an axon out to make connections with other cells and form synapses to become a mature granule cell (4).

Regulation of Neurogenesis in the Dentate Gyrus

The proliferation and survival of neural progenitors in the adult HPC can be influenced in a positive and negative manner by a variety of stimuli. Factors as diverse as stress, odors, neurotrophins, psychoactive drugs such as antidepressants, opioids and alcohol, electroconvulsive therapy, seizures, ischemia, cranial irradiation, physical activity, learning, hormones and age amongst many others have been linked to the regulation of neurogenesis (Kempermann *et al.*, 1998; Van *et al.*, 1999b; Malberg *et al.*, 2000; Malberg & Duman, 2003; Tanapat *et al.*, 2001). Some of these factors have been studied extensively and their role in the regulation of neurogenesis is well defined. For example, environmental enrichment and physical activity are strong positive regulators of neurogenesis (Van *et al.*, 1999b; Kempermann *et al.*, 1997), while stress and age (Cameron *et al.*, 1993; Kempermann *et al.*, 1998) appear to be negative regulators of neurogenesis.

The first report of any factor increasing neurogenesis in the mammalian brain was an enriched environment. In an experimental setting a rodent enriched environment typically consists of a large cage, a large number of animals, toys and a tunnel system. In order to maintain the enrichment aspect novel toys are introduced and tunnel system is rearranged on a regular basis. Mice (Kempermann *et al.*, 1997) and rats (Nilsson *et al.*, 1999) living in an enriched environment exhibited a strong up-regulation of cell proliferation and neurogenesis in the DG of the HPC. The proneurogenic effects of environmental enrichment can be increased further depending on the age of the animal when exposure occurs. When late adolescent/young adult animals live in an enriched environment it enhances the ability of environmental enrichment to up-regulate cellular proliferation and neurogenesis in the DG. In fact, when the morphology of the HPC was examined later in life, a greater number of absolute granule cells was observed (Kempermann *et al.*, 1997). In aged animals (typically 18 months or older in rodents) lower levels of neurogenesis have been observed, however living in an enriched environment counteracts the effects of aging (Kempermann *et al.*, 1998). Kempermann and colleagues demonstrated environment enrichment during aging increases cell proliferation and neurogenesis in the DG (Kempermann *et al.*, 1998). Furthermore, if animals live in an enriched environment during mid age, basal levels of neurogenesis increase as much as five fold in old age.

When experimentation with environmental enrichment began, novel foods were included as apart of the environmental enrichment experience. When similar food was given to mice living either an enriched or control environment, the effect of environmental enrichment was still present. One type of diet however, has been found to have positive effects on neurogenesis specifically, caloric restriction (Lee *et al.*, 2000). As an experimental manipulation caloric restriction usually consists of limiting the amount of food an animal can eat by a third. Caloric restriction is the only factor that has been shown experimentally to increase the life span of animals and it is thought that caloric restriction actually acts as a mild stressor. It is of interest to note while environmental enrichment is a strong positive regulator of adult hippocampal neurogenesis, it does not affect adult neurogenesis in the olfactory system (Brown *et al.*, 2003).

Exposure to an enriched environment increases neurogenesis in the DG of adult rodents, however, environmental enrichment typically includes a running wheel and increased physical activity. Physical activity is known to up-regulate cell proliferation and neurogenesis in the DG. Rodents will take full advantage of the opportunity to exercise on a running wheel during their active phase of their day. Mice have been reported to run between 3 and 8 km per night on a running wheel (Van *et al.*, 1999a; Van *et al.*, 1999b). Voluntary physical activity has been shown to increase the number of progenitor cells and new neurons in the DG of the HPC (Van *et al.*, 1999a; Van *et al.*, 1999b). The effect of running on neurogenesis is acute so that running must continue to effect neurogenesis and once the animal no longer uses the running wheel the effect on neurogenesis will decline. The up-regulation of adult neurogenesis by physical activity also increases long term potentiation (LTP) in the DG and enhances performance on the Morris water maze (MWM) (Van *et al.*, 1999a). The MWM is a behavioral task that assesses memory and learning, but as part of the task the animals are placed into a pool of water and forced to swim. Some have argued that swimming, being physical activity, could also influence the outcome of the task. This point was addressed by Ehninger *et al.* who found involuntary physical activity (swimming in radial arm water maze (RAWM)) had no effect on hippocampal neurogenesis (Ehninger & Kempermann, 2003).

The mechanisms underlying the increase in neurogenesis by physical activity are unknown however, growth factors such as insulin growth factor -1 (IGF-1), vascular endothelial growth factor (VEGF), and brain derived neurotrophic factor (BDNF) have been strongly implicated. IGF-1 levels are increased in the HPC of running animals and running induced increases in cellular proliferation and neurogenesis (Carro *et al.*, 2001; Carro *et al.*, 2000; Trejo *et al.*, 2001). This increase in neurogenesis is blocked by scavenging circulating IGF-1 absent in IGF-1 mutants (Carro *et al.*, 2000). VEGF is necessary for the effects of running on adult hippocampal neurogenesis. Blocking peripheral VEGF abolished the running-induced induction of neurogenesis, however there were no detectable effects on baseline neurogenesis in non-running animal (Fabel *et al.*, 2003). Quantitative polymerase chain reaction analysis revealed BDNF mRNA levels are significantly increased in the DG of running rats (Farmer *et al.*, 2004). BDNF is a key factor involved in modulating neuroplasticity including LTP and neurogenesis. Infusions of BDNF into the lateral ventricles induced neurogenesis originating in the SVZ (Pencea *et al.*, 2001) and BDNF knockout (KO) mice have diminished levels of neurogenesis in the DG (Lee *et al.*, 2002). Like environmental enrichment, physical activity up-regulates adult hippocampal neurogenesis, however, it does not affect adult neurogenesis in the olfactory system (Brown *et al.*, 2003).

Stress severely impairs hippocampal neurogenesis. One of the first studies to link stress to hippocampal neurogenesis was conducted by Gould and colleagues (1992). They found stress increased the number of dying cells in the HPC but that the total number of granule cells in the dentate was not different from non-stressed controls and concluded neurogenesis must be occurring to maintain cellular balance (Gould *et al.*, 1992). They postulated the stress hormone, cortisol in humans and corticosterone in rodents mediates the stress effect on neurogenesis and went on to discover adrenalectomy (removing the adrenal gland hence the source of endogenous corticosterone) led to an up-regulation of neurogenesis and exogenous corticosterone down-regulated cellular proliferation and neurogenesis in the DG (Cameron *et al.*, 1993). Since these early experiments, severe stress has been shown to downregulate cell proliferation and consecutive stages of neuronal development using many different paradigms. Prenatal stress caused learning deficits and had detrimental effects on neurogenesis that lasted well into adulthood (Lemaire *et al.*, 2000). The effects of psychosocial stress on neurogenesis were demonstrated using the resident-intruder model of territorial tree shrews (Gould *et al.*, 1997). Tree shrews are extremely territorial and guard their environment so the introduction of an intruder to the resident's cage is extremely stressful. The territorial tree shrews compete for dominance and soon after the introduction of an intruder a dominant-subordinate relationship is established resulting in elevated cortisol and decreased neurogenesis in the subordinate tree shrew (Gould *et al.*, 1997). Predator odor triggered a stress response in prey and had detrimental effects on cell proliferation. In rodent models, fox odor has been shown to decrease cell proliferation and neurogenesis in the DG (Tanapat *et al.*, 2001). Both acute and chronic restraint stress have been shown to affect the rate of adult hippocampal neurogenesis. Pham and colleagues demonstrated that 6 weeks of daily restraint stress suppressed cell proliferation and attenuated survival of the newly born cells, resulting in a 47% reduction of granule cell neurogenesis (Pham *et al.*, 2003). Neurogenesis is not only affected by environmental stimuli, the absence of stimuli, such as social isolation, negatively regulated neurogenesis. Young rats reared in social isolation for 4-8 weeks showed decreased performance on the MWM and decreased hippocampal neurogenesis (Lu *et al.*, 2003). In the learned helplessness model of depression animals are exposed to an inescapable foot shock using avoidance testing. Exposure to inescapable shock decreased cell proliferation in the HPC, extending previous studies demonstrating downregulation of neurogenesis by exposure to acute stressors (Malberg & Duman, 2003).

The key mechanism underlying the negative impact that stress has on neuroplasticity appears to be stress hormone (glucocorticoid) secretion (Cameron *et al.*, 1993). Acute, severe and sometimes traumatic stress leads to chronically high levels of glucocorticoids and alters the functioning of the hypothalamic-adrenal-pituitary (HPA) axis resulting in disregulation of glucocorticoid secretion and receptor expression. Depression is an example of a clinical condition associated with disturbed regulation of the HPA axis which upsets the circadian rhythm of hormone secretion resulting in chronically elevated glucocorticoid levels and decreased neurogenesis (Jacobs *et al.*, 2000).

Aging is another factor known to have a strong negative influence on neurogenesis. This has been known since the discovery of adult neurogenesis by Altman and Das in 1965. In the original study a progressive decrease in the levels of neurogenesis was observed after puberty and continued into old age (Altman & Das, 1965) and this finding has been since replicated in both rats (Seki & Arai, 1995; Kuhn *et al.*, 1996; Cameron & McKay, 1999; Bizon & Gallagher, 2003), mice (Kempermann *et al.*, 1998) and humans (Eriksson *et al.*, 1998). The highest levels of adult neurogenesis occurred in young adulthood and steadily decreased over the lifespan. In old age (typically 18 months or older in rodents) baseline levels of neurogenesis are extremely low, however, there are ways to enhance neurogenesis in the aging hippocampus. Environment enrichment during aging increases cell proliferation and neurogenesis in the DG, however, the effect of an enriched environment is more robust in young animals (Kempermann *et al.*, 1998). Animals that lived in an enriched environment starting at mid age had five fold increases in basal levels of neurogenesis in old age (Kempermann *et al.*, 1998). Cortisol (or corticosterone in rodents) levels are elevated in aging which likely reduces baseline proliferation and neurogenesis. Adrenalectomy in aged animals restored adult neurogenesis in the DG to a level comparable to that of a much younger age, demonstrating corticosterone is at least in part responsible for the decline in neurogenesis observed in aging (Cameron & McKay, 1999). IGF-1 levels are increased in the HPC running animals and running induced increases in cellular proliferation and neurogenesis (Carro *et al.*, 2001; Carro *et al.*, 2000; Trejo *et al.*, 2001). Similarly, aged animals administered exogenous IGF-1 to restore endogenous IGF-1 levels to that of a younger age and induced neurogenesis above controls thus counteracted the negative effect of aging on neurogenesis (Lichtenwalner *et al.*, 2001).

BDNF is considered a critical secreted factor modulating brain plasticity. Physical activity, which is known to positively regulate neurogenesis and induce LTP, induces hippocampal BDNF mRNA expression. It is thought that BDNF may modulate the effect that physical activity has on LTP and neurogenesis (Farmer *et al.*, 2004). Infusions of BDNF into the lateral ventricles induced neurogenesis originating in the SVZ (Pencea *et al.*, 2001) and BDNF KO mice have diminished levels of hippocampal neurogenesis (Lee *et al.*, 2002). In pathological conditions such as depression, BDNF blocks neurogenesis (which is opposite to healthy animals) and it is now understood one of the critical functions of BDNF is to keep neurogenesis within a physiological range. BDNF function has been implicated in the neurogenesis hypothesis of depression, the idea being that the antidepressants enhance neurogenesis, and BDNF is a key regulator of this mechanism (Jacobs *et al.*, 2000; D'Sa & Duman, 2002). Antidepressants (including selective serotonin reuptake inhibitors (SSRIs)) induce the phosphorylation of CREB, after which CREB binds to the BDNF promoter and induces BDNF transcription. 5-HT_{2A} receptor agonists, such as 2,5-dimethoxy-4-iodoamphetamine (DOI), increase BDNF mRNA expression in the HPC (Vaidya *et al.*, 1997). BDNF is involved in inducing neuronal differentiation possibly through the induction of neuronal nitric oxide synthase (nNOS) which has been shown to stop proliferation and promote differentiation. In vitro BDNF is a differentiation factor that can down-regulate precursor cell proliferation (Cheng *et al.*, 2003).

Hippocampal Neurogenesis and Learning

Memory involves the encoding, storing and recalling of information. The HPC plays a critical role in learning and memory by converting short-term memories into long-term memories and is pivotal in the encoding, consolidation and retrieval of episodic memory (Squire *et al.*, 1992; Squire, 1992). Several studies have investigated the connection between learning and hippocampal neurogenesis. Hippocampal mediated learning and memory has been shown to be related to the generation of new neurons in the adult DG (Van *et al.*, 2002; Nilsson *et al.*, 1999).

It has been postulated only learning tasks which are hippocampal dependant affect progenitor cell proliferation and neurogenesis in the DG (Gould *et al.*, 1999a). This idea has since been demonstrated using a learning task that is easily manipulated to be either hippocampal dependent or independent. Hippocampal-dependent learning can be assessed using trace eye blink conditioning. In trace conditioning the conditioned stimulus (CS), a tone, sounds for 5 seconds, then after a 100-1000 ms interval, the unconditioned stimulus (US) an airpuff or eyelid shock is activated. In this way the CS and US do not overlap. Hippocampal-independent learning can be assessed using delay eyeblink conditioning. In delay eyeblink conditioning the tone (CS) sounds for 5 seconds and in the last 20 ms of the tone sounding the airpuff (US) is activated. In this way the CS and US overlap. Shors and colleagues used both trace and delay eyeblink conditioning to demonstrate that trace eyeblink conditioning, a hippocampal dependent task, is affected by neurogenesis whereas delay eyeblink conditioning is not. Mice were treated with methylazoxymethanol acetate (MAM), an anti-mitotic agent which wipes out the progenitor cell population in the DG and administered BrdU to birth date the cells then performed either trace or delay eyeblink conditioning. In both trace and delay eyeblink conditioning, saline treated mice performed well on the task and had similar numbers of BrdU positive cells in the DG. This is in contrast to mice treated with MAM which produced different results for trace and delay eyeblink conditioning. In trace eyeblink conditioning MAM severely impaired learning and obliterated BrdU incorporation in the DG, whereas, no impairment in learning was observed after delay eyeblink conditioning despite mice being treated with MAM, thus obliterating the progenitor pool and resulted in a dramatic reduction of BrdU positive cells in the DG (Shors *et al.*, 2001).These results clearly indicate that newly generated neurons in the adult DG are affected by the formation of hippocampal-dependent memory.

Only certain types of hippocampal dependent tasks have been shown to be involved in hippocampal neurogenesis (Shors *et al.*, 2002). This was demonstrated using two different learning paradigms known to require the HPC, the spatial navigation task and trace fear conditioning. Similar to the study mentioned earlier, mice were treated with MAM and BrdU then performance on either behavioral task was assessed. The spatial navigation task is performed in the MWM and required the mouse to use spatial cues in the environment (like a black square on a wall) to navigate to and find the platform. Over trials mice learned where the platform was located and spent less time trying to find it. MAM failed to result in impairment in escape latency but did significantly decreased BrdU+ cells in the SGZ, demonstrating that hippocampal progenitor cell proliferation is not essential for this hippocampal-dependent task (Shors *et al.*, 2002). In a separate group of mice trace fear conditioning, which like trace eyeblink conditioning involves a time gap between CS and US presentation was performed. In trace fear conditioning MAM severely impaired learning and significantly diminished BrdU incorporation in the DG, thus providing more evidence for the involvement of trace conditioning in hippocampal neurogenesis (Shors *et al.*, 2002). The above experiments clearly demonstrate that some forms of learning are dependent on the HPC but not all hippocampal-dependent learning tasks require neurogenesis.

The HPC is involved in the formation and expression of memory in the passive avoidance task in rats (Cahill & McGaugh, 1998). The logic underlying the passive avoidance (PA) task is that animals associate a particular environment with an unpleasant foot shock and learn by avoiding the environment they can avoid the aversive foot shock. Consequently, an increase in response latency is thought to reflect the strength of the memory for the aversive event (Sahgal & Mason, 1985). Specifically, the multi-herbal formula BR003 increased response latency, and hence the memory of the foot shock while also increasing the number of BrdU positive cells in the DG (Oh *et al.*, 2006). The PA task is relatively quick and simple but is limited in the information it provides regarding memory, that latencies increase following shock. A modified version of PA, the active avoidance paradigm measures acquisition (learning), retention (memory) and the extinction of the conditioned response.

Active avoidance is a fear-motivated associative avoidance task. In this task the mouse has to learn to predict the occurrence of an aversive event (shock) based on the presentation of a specific stimulus (tone), in order to avoid the aversive event by moving to a different compartment. The measures recorded include number of avoidances (the mouse crossing to the other compartment during the warning signal), number of non-responses (the mouse failing to cross to the other compartment during the trial), response latency (latency to avoid or escape), number of intertrial responses (i.e., crossing the barrier within the intertrial interval), and serve as an index of learning which allows memory to be assessed.

Many studies supported the role of the HPC in active avoidance learning. LTP via electrical stimulation to the perforant pathway is negatively correlated to learning in the shuttle box avoidance task, suggesting active avoidance training lowered the threshold frequency to induce LTP in the DG (Ramirez & Carrer, 1989). Active avoidance learning increased the length of the postsynaptic density in the molecular cell layer of the DG (Van *et al.*, 1992) and increased immunoreactivity for muscarinic receptors in the granular cell layer (Van der Zee & Luiten, 1999). Two-way Active avoidance also increased synthesis of BDNF (Ulloor & Datta, 2005) and cAMP response element binding (CREB) in the dorsal HPC (Saha & Datta, 2005). Rats that learned the active shock avoidance task (responders) had similar levels of Brdu positive and Ki67 positive cells in the DG as non-responders, suggesting ASA has no effect on hippocampal progenitor cell proliferation (Van der *et al.*, 2005).

Active avoidance testing is commonly used following exposure to severe inescapable foot shock in the learned helplessness model of depression. Exposure to inescapable foot shock decreased progenitor cell proliferation in the DG and this effect is reversed by chronic treatment with fluoxetine (Malberg & Duman, 2003). One target of antidepressant treatment is BDNF since antidepressants not only increase the expression of CREB in the rat HPC (Nibuya *et al.*, 1996) but also increase the expression of BDNF (Nibuya *et al.*, 1995). BDNF produced antidepressant like effects in the learned helplessness model of depression (Shirayama *et al.*, 2002).

Assessing Neurogenesis

The systemic injection of thymidine, radioactively labeled with tritium was the first method developed to label dividing cells (Messier *et al.*, 1958). Once in the bloodstream, tritiated thymidine competes with endogenous thymidine in all cells in the S phase of cell division and is permanently incorporated into the DNA. Labeled thymidine has a short half-life in vivo and labels all cells in the process of cell division when the label is injected. At a later time point, tissue sections are prepared and coated with a photo emulsion. The radiation from the labeled thymidine molecules blackens the photo emulsion, thus making visible the typical grains of thymidine autoradiography. Utilizing the tritiated thymidine method (Sidman *et al.*, 1959; Messier *et al.*, 1958; Messier & Leblond, 1960) Joseph Altman was able to demonstrate that the SVZ and the DG of the HPC produce new neurons throughout the lifespan (Altman, 1962; Altman & Das, 1965; Altman, 1969).

BrdU is a false base that competes with endogenous thymidine and becomes permanently incorporated in the DNA during the S phase of the cell cycle. BrdU is typically administered via injections of usually 50-250 mg/kg in a single bout or over several days depending on the experimental paradigm (Corotto *et al.*, 1993). BrdU is advantageous because it is a permanent marker so any cells that express BrdU can be directly related to the time BrdU was administered thus providing the birth date of the cell. It is important to note BrdU can be incorporated into cells that are on the verge of dying when cell death related mechanisms trigger DNA repair,therefore proper controls need to be included such as immunohistochemical stains for apoptosis (caspase-3 or TUNEL) and proliferative markers (Ki67) to determine if a cell is truly proliferative.

The rate of proliferation can be differentiated from the rate of survival by manipulating time between BrdU injection and sacrifice so proliferating cells can be determined by sacrificing animals 24 hours after a BrdU injection. In this way BrdU has time to incorporate into the cell but the cell does not have time to differentiate into a neuron, a process which takes a minimum of 72 hours. Survival can be determined by taking the brains of animals days, weeks or even months after BrdU injection. The phenotypic fate of the cell is determined in the survival condition by double labeling BrdU with another marker. Table 1 presents a summary of the common markers used to determine the phenotype of neural progenitors.

Marker	Significance	Reference
Ki67	Proliferation; late G1, S, G2 and M phases nuclear	(Scholzen & Gerdes, 2000)
Doublecortin (DCX)	Immature neuron; microtubule-associated protein enriched in migratory neuronal cells. Early neuronal marker with lineage determined and limited self-renewal dendritic	(Meyer *et al.*, 2002)
III β-tubulin (Tuj1)	Immature neuron; Tubulin protein soma and processes	(Uittenbogaard & Chiaramello, 2002)
Calretinin (CRT)	Immature neurons; calcium binding protein transiently	(Brandt *et al.*, 2003)
Neuronal nuclei (NeuN)	Mature neurons; mostly in nuclei but can be detected in cytoplasm nucleus	(Mullen *et al.*, 1992)
Glial Fibrillary Acidic Protein (GFAP)	Intermediate filament protein expressed in astrocytes.	(Fuchs & Weber, 1994)

Table 1. Antibodies used to assess phenotypic fate of progenitors.

If the cell expresses Ki67 it is an early progenitor since Ki67 is a protein expressed the G1, S, G2 and M phases of the cell cycle (Scholzen & Gerdes, 2000). Cells that express doublecortin (DCX), β-tubulin III (III β-tubulin, Tuj1), or calretinin (CRT) are immature neurons. DCX is a microtubule associated protein transiently expressed in immature neurons (Meyer *et al.*, 2002), Tuj1 marks tubulin in microtubules (Uittenbogaard & Chiaramello, 2002) and CRT is a calcium binding protein transiently expressed in immature neurons and is expressed in the developing neuron at a stage where DCX expression dissipates (Brandt *et al.*, 2003). The best and most widely used marker to identify mature neurons is neuronal nuclei (NeuN) (Mullen *et al.*, 1992). The expression of NeuN is restricted to post-mitotic neurons and is predominately located in the nucleus of neurons although it can occasionally be observed in the neurites. In order to convincingly demonstrate neurogenesis, cells are double labeled with BrdU plus NeuN, which clearly demonstrates that the cell was born around the time of BrdU injection and survived to differentiate into a neuron. Cell survival depends on many factors including the ability of the cell to form dendrites, an axon, synthesize neurotransmitter, receptors and establish functional connections with other cells. Cells that don't establish functional connections will most likely die.

It is possible to assess neurogenesis using methods other than the BrdU and tritiated thymidine methods. Using immunohistochemical and immunofluorescent techniques, cells can be stained for markers of immature neurons that are transient and only present in newly formed neurons. Brandt and colleagues (2003) elegantly demonstrated this method by defining time periods of development in which cells express particular markers double-labeled with BrdU (Brandt *et al.*, 2003). BrdU is still the only way to birth date cells so for establishing the method it was essential to know the exact age of cells. The expression of CRT plus BrdU positive cells was greatest 1 to 2.5 weeks after BrdU injection and the number of double-labeled cells was negligible at 4 weeks, demonstrating CRT is transient. If a cellexpressed DCX or CRT, that cell can be positively identified as an immature neuron, thus estimates of DCX or CRT positive cells in the DG represent estimates of neurogenesis.

Serotonergic Innervation in the Dentate Gyrus

Serotonin (5-HT) is a modulatory neurotransmitter in the central nervous system which is important in the regulation of vital brain functions such as feeding (Lucki, 1992), thermoregulation (Feldberg & Myers, 1964), sleep (Jouvet, 1967) and aggression (Sheard, 1969). In psychopathological states such as depression (Pinder & Wieringa, 1993), eating disorders (Leibowitz & Shor-Posner, 1986) and anxiety serotonergic signaling is disturbed.

In the mammalian brain 5-HT is produced by neurons in the raphe nucleus (RN) which project to many areas of the brain via the medial forebrain bundle (MFB) (Azmitia & Segal, 1978; Parent *et al.*, 1981). Neurons from RN innervate virtually all brain areas with dense innervation occurring in the HPC, cerebral cortex, striatum, hypothalamus, thalamus, septum and olfactory bulb (Jacobs & Azmitia, 1992; Leger *et al.*, 2001). The innervation of serotonergic fibers to areas within the HPC is variable (Moore & Halaris, 1975; Vertes *et al.*, 1999; Bjarkam *et al.*, 2003). The DG is innervated with serotonergic fibers in both the molecular layer and the hilus with particularly dense innervation projecting to the SGZ where they synapse with interneurons (Halasy & Somogyi, 1993).

5-HT activates fifteen known receptors, many of which are expressed in the DG (El *et al.*, 1989; Tecott *et al.*, 1993; Vilaro *et al.*, 1996; Djavadian *et al.*, 1999; Clemett *et al.*, 2000; Kinsey *et al.*, 2001). Most of the 5-HT receptors interact with G proteins except for the 5-HT$_{3A}$ receptors, which are ligand-gated ion channel receptors. The 5-HT$_3$ receptors (subtypes 5-HT$_{3A}$ and 5-HT$_{3B}$) are ligand-gated Na$^+$ ion channels and their activation leads to the depolarization of neurons (Barnes & Sharp, 1999). The 5-HT$_1$ family of receptors (including subtypes 5-HT$_{1A}$, 5-HT$_{1B}$, 5-HT$_{1D}$, 5-HT$_{1E}$ and 5-HT$_{1F}$) are coupled to the G$_i$ protein which, when activated decreases the activity of adenylyl cyclase thus decreasing the rate of formation of cyclic adenosine monophosphate (cAMP). Activation of 5-HT$_1$ receptors can lead indirectly to the opening of K$^+$ channels therefore increasing the conductance of the cell membrane for K$^+$ ions. Activation of 5-HT$_4$, 5-HT$_6$, 5-HT$_7$, receptors are coupled to G$_s$ proteins which have the opposite effect. They increase the activity of adenylyl cyclase, increase the rate of cAMP formation and decrease K$^+$ conductance (Thomas *et al.*, 2000; Raymond *et al.*, 2001). The 5-HT$_2$ receptors (including subtypes 5-HT$_{2A}$, 5-HT$_{2B}$, 5-HT$_{2C}$) are coupled to G$_q$ proteins and activate phospholipase C (PLC), increasing the rate of formation of inositol triphosphate (IP$_3$) and diacylglycerol leading to the increased formation of protein kinase C (PKC) (Kurrasch-Orbaugh *et al.*, 2003; Ananth *et al.*, 1987).

Serotonin and Neurogenesis in the Dentate Gyrus

While several factors regulate the rate of generation of new cells in the adult DG, one of the most important known factors is 5-HT. Malberg and colleagues found increased levels of 5-HT resulted in the increased rate of proliferation of neural progenitors in the DG (Malberg *et al.*, 2000). Administering 5,7-dihydroxytryptamine (5,7-DHT), a serotonergic neurotoxin into the RN and caused the destruction of axons and serotonergic cells and resulted in a decreased in the number of BrdU-labeled cells in the DG (Brezun & Daszuta, 1999). The 5,7-DHT lesion resulted in around a 60% depletion of the serotonergic innervation to the DG which lasted for one month. After two months, reinnervation to the DG was observed with the sprouting of serotonergic axons so that by the third month there was no observable difference between the 5,7-DHT and vehicle in newly generated cells or serotonergic innervation (Brezun & Daszuta, 2000).

Many serotonergic receptors have been implicated in the regulation of neurogenesis in the DG. In vitro, when the 5-HT$_{1A}$ receptor agonist, 8-OH-DPAT was added to a medium in which cultured fibroblasts transfected with the 5-HT$_{1A}$ receptor were present, the rate of cell divisions increased (Varrault *et al.*, 1992). In vivo, 5-HT$_{1A}$ receptor antagonists (NAN-190, *p*-MPPI and WAY-100635) decreased the number of progenitors in the DG by approximately 30% (Radley & Jacobs, 2002) and injections of 5-HT$_{1A}$ receptor agonists increased the number of BrdU positive cells in the DG (Santarelli *et al.*, 2003). Similarly, Banasr and colleagues showed various 5-HT$_1$ receptor agonists increase the number of BrdU labeled cells in the subgranular layer. Acute administration of the 5-HT$_{2A/C}$ receptor agonist 2,5-dimethoxy-4-iodoamphetamine (DOI), 5-HT$_{2C}$ receptor agonist RO 600175, and 5-HT$_{2C}$ receptor antagonist SB 206553 had no effect of cell proliferation in the HPC, whereas the 5-HT$_{2A/C}$ receptor antagonist ketanserin produced a 63% decrease in BrdU incorporation (Banasr *et al.*, 2004). A recent study found acute ketanserin decreased proliferation whereas chronic ketanserin increased proliferation in the DG (Jha *et al.*, 2008). No effect on proliferation in the DG was observed after DOI or lysergic acid diethylamide (LSD) were administered either acutely or once daily for seven consecutive days (chronic) (Jha *et al.*, 2008).

The 5-HT$_{2A}$ receptor is involved in the regulation of BDNF in the HPC (Vaidya *et al.*, 1997). DOI alone and in combination with selective 5-HT$_{2A}$ and 5-HT$_{2C}$ receptor antagonists decreased the expression of BDNF mRNA in the HPC. Interestingly, the decrease in BDNF mRNA expression was blocked by the 5-HT$_{2A}$ receptor antagonist but not the 5-HT$_{2C}$ receptor antagonist, implicating the 5-HT$_{2A}$ receptor in the regulation of BDNF expression. In addition, the stressinduced reduction in BDNF expression in the HPC was blocked by a 5-HT$_{2A/C}$ receptor antagonist (Vaidya *et al.*, 1997).

Psilocybin (PSOP)

PSOP (4-phosphoryloxy-*N,N*-dimethyltryptamine) is the main active agent in "magic mushrooms" and is categorized as a indole hallucinogen. First isolated from *Psilocybe mexicana*, a mushroom from Central America by Albert Hofmann in 1957, PSOP was then produced synthetically in 1958 (Hofmann *et al.*, 1958a; Hofmann *et al.*, 1958b). PSOP is converted into the active metabolite psilocin (4-hydroxy-*N,N*-dimethyltryptamine) which may produce some of the psychoactive effects of PSOP. The chemical structure of PSOP ($C_{12}H_{17}N_2O_4P$) and the metabolite, psilocin ($C_{12}H_{16}N_2O$) are similar to 5-HT ($C_{10}H_{12}N_2O$), the main neurotransmitter which they affect (see Figure 1.3).

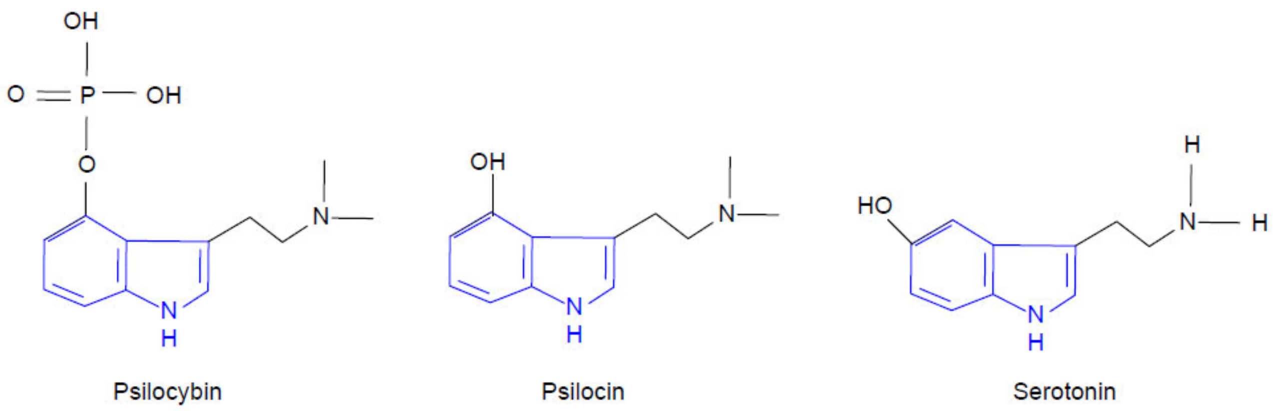

Figure 1.3. Chemical structure of Psilocybin, Psilocin and Serotonin.

In vivo studies in mice have shown the LD_{50} of PSOP via intravenous administration to be 280 mg/kg (Cerletti & Konzett, 1956; Cerletti, 1959). Autonomic effects of 10 mg/kg/sc in mice, rats, rabbits, cats and dogs include mydriasis, piloerection, irregularities in heart and breathing rate and hyperglycemic and hypertonic effects (Cerletti & Konzett, 1956; Cerletti, 1959). These effects were interpreted as an excitatory syndrome caused by stimulation of the sympathetic nervous system with one large exception being the absence of hyperlocomotion (Monnier, 1959).

PSOP exerts psychoactive effects by altering serotonergic neurotransmission by binding to 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2A} and 5-HT_{2C} receptor subtypes (Passie *et al.*, 2002). PSOP binds to the 5-HT_{2A} receptor (Ki = 6 nM) with high affinity and to a much lesser extent to the 5-HT_{1A} receptor subtype (Ki = 190 nM) (McKenna *et al.*, 1990). However, PSOP has a lower affinity for 5-HT_{2A} and 5-HT_{2C} receptors compared to lysergic acid diethylamide (LSD), a similar indole hallucinogen (Nichols, 2004). In contrast to LSD, PSOP has a very low affinity to DA receptors and only extremely high doses affect NE receptors. PSOP has been shown to induce schizophrenia-like psychosis in humans, a phenomenon attributed to the action of PSOP through 5-HT_{2A} receptor action. Specifically, human volunteers were pretreated with ketanserin, an antagonist to the $5\text{-HT}_{2A/C}$ receptor, then administered 0.25 mg/kg p.o. PSOP and the psychotomimetic effects of PSOP were completely blocked (Vollenweider *et al.*, 1998). Since blocking the 5-HT_{2A} receptor prevented the psychotropic effect of PSOP it appears as though the actions of PSOP are mediated via the activation of 5-HT_{2A} receptors. A recent study tested PSOP-induced stimulus control and found 5-HT_{2A} receptor antagonists prevented rats from recognizing PSOP in a drug discrimination task, an effect which was not observed with 5-HT_{1A} receptor antagonists (Winter *et al.*, 2007). Repeated daily administration of PSOP selectively downregulated 5-HT_{2A} receptors in the rat brain (Buckholtz *et al.*, 1990; Buckholtz *et al.*, 1988; Buckholtz *et al.*, 1985). PSOP binds to the 5-HT_{2A} receptor and stimulates arachidonic acid and consequently, the PI pathway resulting in the activation of PKC (Kurrasch-Orbaugh *et al.*, 2003). This dissertation sought to evaluate the involvement of the 5-HT_{2A} receptor in the regulation of hippocampal neurogenesis and hippocampal-dependent learning.

Specific Aims

The present study investigated the role of 5-HT_{2A} receptor on hippocampal neurogenesis and hippocampal-dependent learning. The effects of acute and chronic 5-HT_{2A} receptor agonists and an antagonist on the survival and phenotypic fate of progenitor cells in the DG were assessed using immunofluroescent techniques.

In addition the effects of acute PSOP on trace fear conditioning were used to assess learning and memory.

Specific Aim 1

To evaluate the effect of acute 5-HT$_{2A}$ receptor agonists and an antagonist on the survival and phenotypic fate of hippocampal progenitor cells. It was hypothesized PSOP and 251-NBMeO, both 5-HT$_{2A}$ receptor agonists positively regulate neurogenesis in the DG of the HPC, and ketanserin, a 5-HT$_{2A/C}$ receptor antagonist downregulates hippocampal neurogenesis.

Specific Aim 2

To elucidate whether PSOP affects learning and memory using the trace fear conditioning paradigm. It was hypothesized acute exposure to PSOP would enhance hippocampal-dependent learning and ketanserin would impair learning on the trace fear conditioning task.

Chapter Two

Involvement of the 5HT$_{2A}$ receptor in the Regulation of Adult Neurogenesis in the Mouse Hippocampus

Abstract

Selective serotonin uptake inhibitors (SSRIs) are known to stimulate the production of new neurons in the hippocampus (HPC) by increasing synaptic concentration of serotonin (5-HT). The delay in the appearance of antidepressant effects corresponds to the time required to generate new neurons. However, it is not clear which of the many serotonergic receptors in the HPC are responsible for the enhanced neurogenesis. The current study evaluated the effects of the acute and chronic administration of 5-HT$_{2A}$ agonists psilocybin and 251-NBMeO and the 5-HT$_{2A/C}$ antagonist ketanserin on hippocampal neurogenesis. To investigate the effects of acute drug administration mice received a single injection of varying doses of psilocybin, 251-NBMeO, ketanserin or saline followed by i.p. injections of 75 mg/kg bromodeoxyuridine (BrdU) for 4 consecutive days followed by euthanasia two weeks later. For chronic administration 4 injections of psilocybin, ketanserin or saline were administered weekly over the course of one month. On days following drug injections mice received an injection of 75 mg/kg BrdU and were euthanized two weeks after the last drug injection. Unbiased estimates of BrdU+ and BrdU/NeuN+ cells in the dentate gyrus (DG) revealed a significant dose dependent reduction in the level of neurogenesis after acute 5-HT$_{2A}$ receptor agonist or antagonist administration. Interestingly, chronic administration of psilocybin increased the number of newborn neurons in the DG while the antagonist suppressed hippocampal neurogenesis, suggesting the 5-HT$_{2A}$ receptor appears to be involved in the regulation of hippocampal neurogenesis.

Introduction

Evidence suggests neurogenesis occurs throughout the lifespan in two specific regions of the adult brain, the subventricular zone (SVZ) and the subgranular zone (SGZ) of the DG (Altman J, 1962; Altman & Das, 1965; Altman J, 1969). The proliferation and survival of neural progenitors in the adult HPC can be influenced by a variety of stimuli including stress, age, physical activity and depression (Gould *et al.*, 1992; Kempermann *et al.*, 1998; Van *et al.*, 1999b; Malberg *et al.*, 2000). Antidepressant medications such as selective 5-HT uptake inhibitors (SSRIs) enhance the production of new born neurons in the DG of the HPC (Malberg *et al.*, 2000). However, this effect is time specific with chronic administration (14 days or more) enhancing neurogenesis but not acute treatment (Malberg *et al.*, 2000). Interestingly, there is a delay in the appearance of antidepressant effects which corresponds to the time required to generate new neurons (Santarelli *et al.*, 2003) suggesting an enhancement of neurogenesis may mediate the behavioral effects of antidepressants.

The requirement of chronic administration of antidepressant medications to enhance neurogenesis is likely due to number of factors. Antidepressant treatments upregulated the expression of brain-derived neurotrophic factor (BDNF) in the HPC (Nibuya *et al.*, 1995). BDNF knockout mice have diminished levels of neurogenesis in the DG (Lee *et al.*, 2002) and infusions of BDNF into the lateral ventricles induced neurogenesis originating in the SVZ (Pencea *et al.*, 2001).

The involvement of 5-HT in the regulation of neurogenesis may be mediated through different 5-HT receptor subtypes expressed on cells in the neurogenic microniche (Barnes & Sharp, 1999). The 5-HT$_{2A}$ receptor is involved in the regulation of BDNF in the HPC (Vaidya *et al.*, 1997). 2,5-dimethoxy-4- iodoamphetamine (DOI), a 5-HT$_{2A/C}$ receptor agonist decreased the expression of BDNF mRNA in the HPC (Vaidya *et al.*, 1997). Interestingly, the decrease in BDNF mRNA expression was blocked by the 5-HT$_{2A}$ receptor antagonist but not the 5-HT$_{2C}$ receptor antagonist, implicating the 5-HT$_{2A}$ receptor in the regulation of BDNF expression in the HPC (Vaidya *et al.*, 1997). Acute administration of DOI, 5-HT$_{2C}$ receptor agonist RO 600175, or the 5-HT$_{2C}$ receptor antagonist SB 206553 had no effect on cell proliferation, whereas the 5-HT$_{2A/C}$ receptor antagonist ketanserin produced a 63% decrease in BrdU incorporation (Banasr *et al.*, 2004). A recent study found acute ketanserin decreased proliferation whereas chronic ketanserin increased proliferation in the DG (Jha *et al.*, 2008). No effect on proliferation in the DG was observed after DOI or lysergic acid diethylamide (LSD) were administered either acutely or once daily for seven consecutive days (chronic) (Jha *et al.*, 2008). However, daily doses of LSD or psilocybin (PSOP) produce rapid tolerance to the drug and resulted in a selective downregulation of the 5-HT$_{2A}$ receptor (Buckholtz *et al.*, 1990; Buckholtz *et al.*, 1985). Therefore, in order to investigate the role of the 5-HT$_{2A}$ receptor in the regulation of hippocampal neurogenesis the current study evaluated the effects of acute and repeated intermittent administration of 5-HT$_{2A}$ agonists and the 5-HT$_{2A/C}$ antagonist ketanserin on hippocampal neurogenesis.

Materials and Methods

Subjects

C57BL/6J male mice (30-40g) were housed in standard laboratory cages and left undisturbed for 1 week after arrival at the animal facility. All mice had unlimited access to water and laboratory chow and were maintained in a temperature and humidity controlled room on a 12:12 light/dark cycle with light onset at 7:00 AM. All National Institutes for Health (NIH) guidelines for the Care and Use of Laboratory Animals were followed (National Institutes of Health, 2002).

Drugs

251-NBMeO was synthesized in the laboratory of Dr David Nichols (Braden *et al.*, 2006). PSOP was provided by Dr Francisco Moreno from University of Arizona. Ketanserin (+)-tartrate salt (#S006, St. Louis, MO) and 5-Bromo-2′-deoxyuridine (#B5002, St. Louis, MO) were supplied by Sigma-Aldrich Inc.

General Procedure

Acute Administration: A total of 48 C57BL/6 mice received a single injection of 0.1 mg/kg PSOP (n=6), 0.5 mg/kg PSOP (n=6), 1.0 mg/kg PSOP (n=6), 0.1 mg/kg 251-NBMeO (n=6), 0.3 mg/kg 251-NBMeO (n=6), 1.0 mg/kg 251-NBMeO (n=6), 1.0 mg/kg ketanserin (n=6) or saline (n=6). Mice received an intraperitoneal (i.p.) injection of 75 mg/kg BrdU once daily for 4 days following drug administration and were euthanized two weeks after the last drug injection. Mice were euthanized with nembutal then transcardially perfused with 0.9% saline followed by 4% paraformaldehyde. Brains were stored in 4% paraformaldehyde, transferred to 20% sucrose solution and sectioned coronally using a cryostat (Leica, Germany) at 30μM in a 1:6 series and stored in 24-well plates in cryoprotectant at -20°C. Repeated Intermittent Administration: A total of 31 C57BL/6 mice received 4 i.p. injections of either 0.5 mg/kg PSOP (n=6), 1.0 mg/kg PSOP (n=7), 1.5 mg/kg PSOP (n=6), 1.0 mg/kg ketanserin (n=6) or 0.9% saline solution (n=6) over the course of one month on days 1, 8, 15, and 22. Each day following drug administration 75 mg/kg BrdU was injected i.p. All mice were euthanized two weeks after the last drug injection according to the above procedures.

Immunofluorescence

For the double labeling of progenitor cells in the DG free-floating sections were denatured using 2N HCl and neutralized in 0.15M borate buffer then washed in PBS. Tissue was blocked in PBS+ (PBS, 10% normal goat serum, 1% 100x Triton X, 10% BSA) for 1 hour at 4°C and incubated for 48 hours at 4°C in an antibody cocktail of rat monoclonal anti-BrdU (AbD Serotec, Raleigh NC, #OBT0030G, 1:100) plus mouse anti-NeuN (Chemicon, 1:100) in PBS. Sections were washed in PBS and incubated in a secondary antibody cocktail of goat anti-rat IgG Alexa Fluor 594 (1:1000, Invitrogen, Eugene OR) plus goat anti-mouse (1:400, Invitrogen) and coated with vectorshield mounting medium (Invitrogen).

Quantitation

For the quantification of doubled labeled cells using immunofluroescence, the number of BrdU+ and BrdU/NeuN+ labeled cells were estimated using every 6th section taken throughout the DG (every 180 microns). To avoid counting partial cells a modification to the optical dissector method was used so that cells on the upper and lower planes were not counted. The number of BrdU+ cells counted in every 6th section was multiplied by 6 to get the total number of BrdU+ or BrdU/NeuN+ cells in the DG (Shors *et al*. 2002). Positive labeling was verified by confocal microscopy (Zeiss).

Design and analyses

Separate one-way analyses of variance (ANOVA) were used to evaluate the acute and chronic effects of 5-HT$_{2A}$ receptor agonists and an antagonist on hippocampal neurogenesis. For acute drug administration separate one-way ANOVA was used to determine the effects of Drug [PSOP (saline, 0.1 mg/kg, 0.5 mg/kg, 1.0 mg/kg), 251-NBMeO (saline, 0.1 mg/kg, 0.3 mg/kg, 1.0 mg/kg)] and a two-tailed *t*-test (saline, 1.0 mg/kg ketanserin) was used to establish differences in cell survival and neurogenesis. For chronic drug administration a separate one-way ANOVA was used to determine the effects of Dose (saline, 0.5 mg/kg PSOP, 1.0 mg/kg PSOP, 1.5 mg/kg PSOP, 1.0 mg/kg ketanserin) on cell survival and neurogenesis. When appropriate, post hoc analyses such as Bonferroni were used to isolate Drug effects. All statistical analyses were determined significant at the 0.05 alpha level.

Results

Effects of Acute Administration of 5-HT$_{2A}$ receptor agonists and an antagonist in vivo on Cell Survival and Neurogenesis in the Hippocampus

In order to investigate the effects of acute PSOP administration on cell survival and neurogenesis mice (n = 6-7 per condition) were injected with PSOP (0.1, 0.5, or 1.0 mg/kg), 251-NBMeO (0.1 mg/kg, 0.3 mg/kg, 1.0 mg/kg), ketanserin (1.0 mg/kg) or 0.9% saline solution then received 75 mg/kg BrdU once daily for 4 days following drug administration followed by euthanasia two weeks after the last drug injection. A one-way ANOVA detected significant differences in the total number of surviving BrdU+ cells in the DG as a result of acute PSOP treatment [$F(3,20)=6.64$, $p=0.003$]. As can be seen in Figure 2.1A a significant decrease in the number of surviving BrdU+ cells was observed after 1.0 mg/kg PSOP compared to saline (indicated by *).

The phenotypic fate of surviving cells was determined by immunofluorescent labeling of BrdU and NeuN. A one way ANOVA revealed a significant effect of dose on the number of double labeled neurons in the DG [$F(3,20)=10.26$, $p=0.0003$]. As can be seen in Figure 2.1B, acute administration of 1.0 mg/kg PSOP significantly diminished the number of BrdU/NeuN+ cells compared to saline ($p<0.05$). These data suggest acute administration of 1.0 mg/kg PSOP, a 5-HT$_{2A}$ agonist downregulated neurogenesis in the DG.

A one-way ANOVA detected significant differences in the total number of surviving BrdU+ cells in the DG as a result of acute 251-NBMeO treatment [$F(3,20)=9.00$, $p=0.0004$]. There was a significant decrease in the number of surviving BrdU+ cells after acute administration of 0.1, 0.3 and 1.0 mg/kg 251- NBMeO compared to saline (see figure 2.3A, indicated by *).

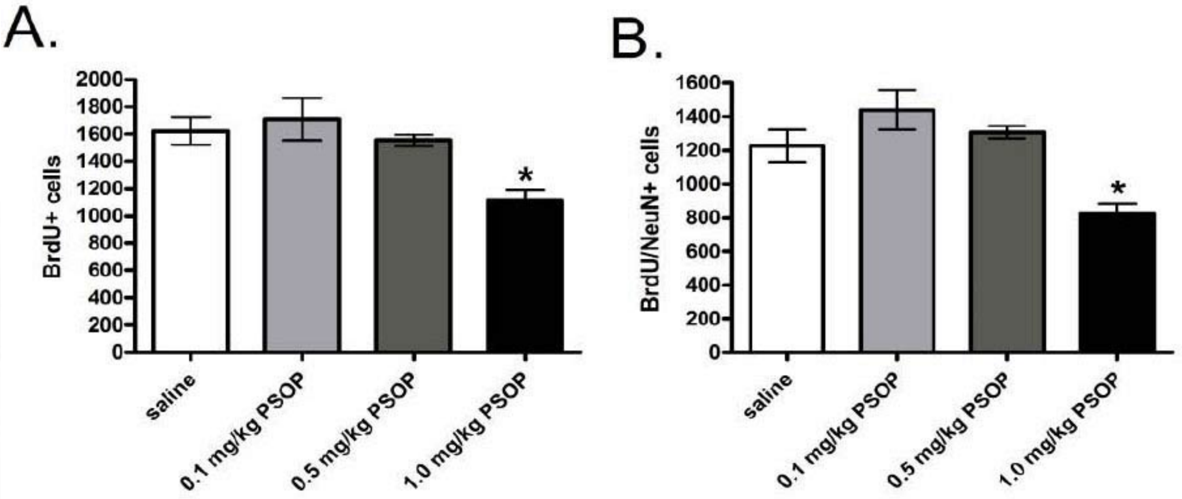

Figure 2.1. Effect of Acute PSOP Administration on Hippocampal Neurogenesis. Mice (*n* = 6 per condition) were injected with PSOP (0.1, 0.5, or 1.0 mg/kg) or saline then received 75 mg/kg BrdU once daily for 4 days following drug administration followed by euthanasia two weeks after drug injection. A) The total number of BrdU+ cells in the DG were significant diminished after a single injection of 1.0 mg/kg PSOP ($p<0.05$). B) Acute administration of 1.0 mg/kg PSOP significantly diminished the number of BrdU/NeuN+ cells compared to saline ($p<0.05$). These data suggest acute administration of 1.0 mg/kg PSOP, a 5-HT_{2A} agonist downregulated neurogenesis in the DG of the HPC.
* indicates a significant difference from saline.

Figure 2.2. Representative photomicrographs showing the effects of acute PSOP on hippocampal neurogenesis. NeuN+ cells (left), BrdU+ cells (center) and NeuN/BrdU+ cells (right). Saline (A-C), 0.1 mg/kg PSOP (D-F), 0.5 mg/kg PSOP (G-I) and 1.0 mg/kg PSOP (J-L). Scale = 50 µM.

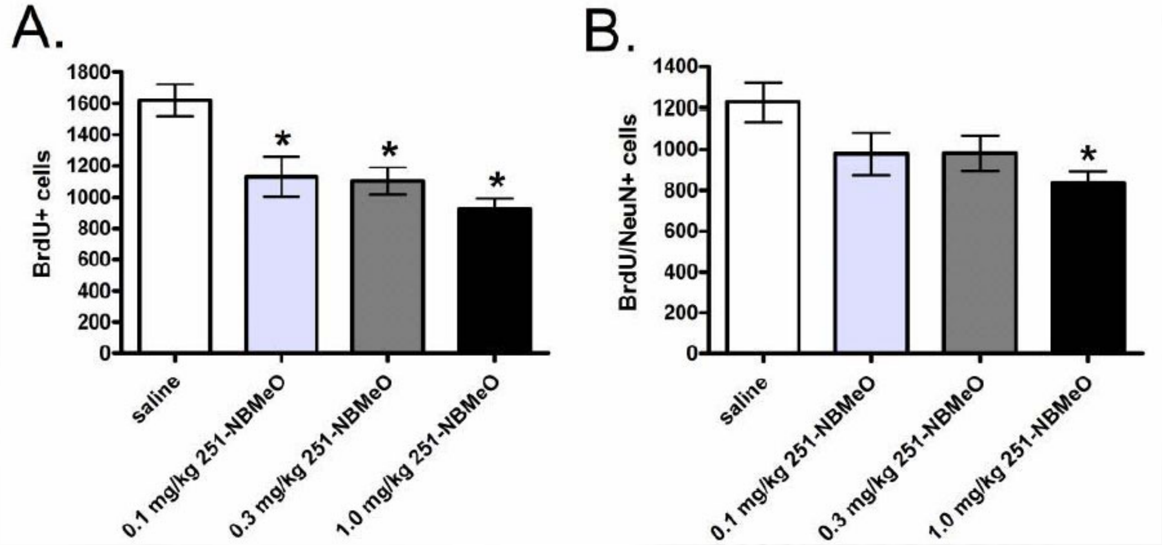

Figure 2.3. Effect of the selective 5-HT_{2A} receptor agonist, 251-NBMeO on hippocampal neurogenesis. Mice (*n* = 6 per condition) were injected with 251- NBMeO (0.1, 0.3, or 1.0 mg/kg) or saline then received 75 mg/kg BrdU once daily for 4 days following drug administration followed by euthanasia two weeks after drug injection. A) There was a significant decrease in the total number of BrdU+ cells in the DG after the administration of 251-NBMeO ($p<0.05$). B) The number of new born neurons was significantly decreased after 1.0 mg/kg of 251- NBMeO compared to saline ($p<0.05$), suggesting acute administration of the 5-HT_{2A} receptor agonist downregulated neurogenesis in the DG of the HPC.
* indicates a significant difference from saline.

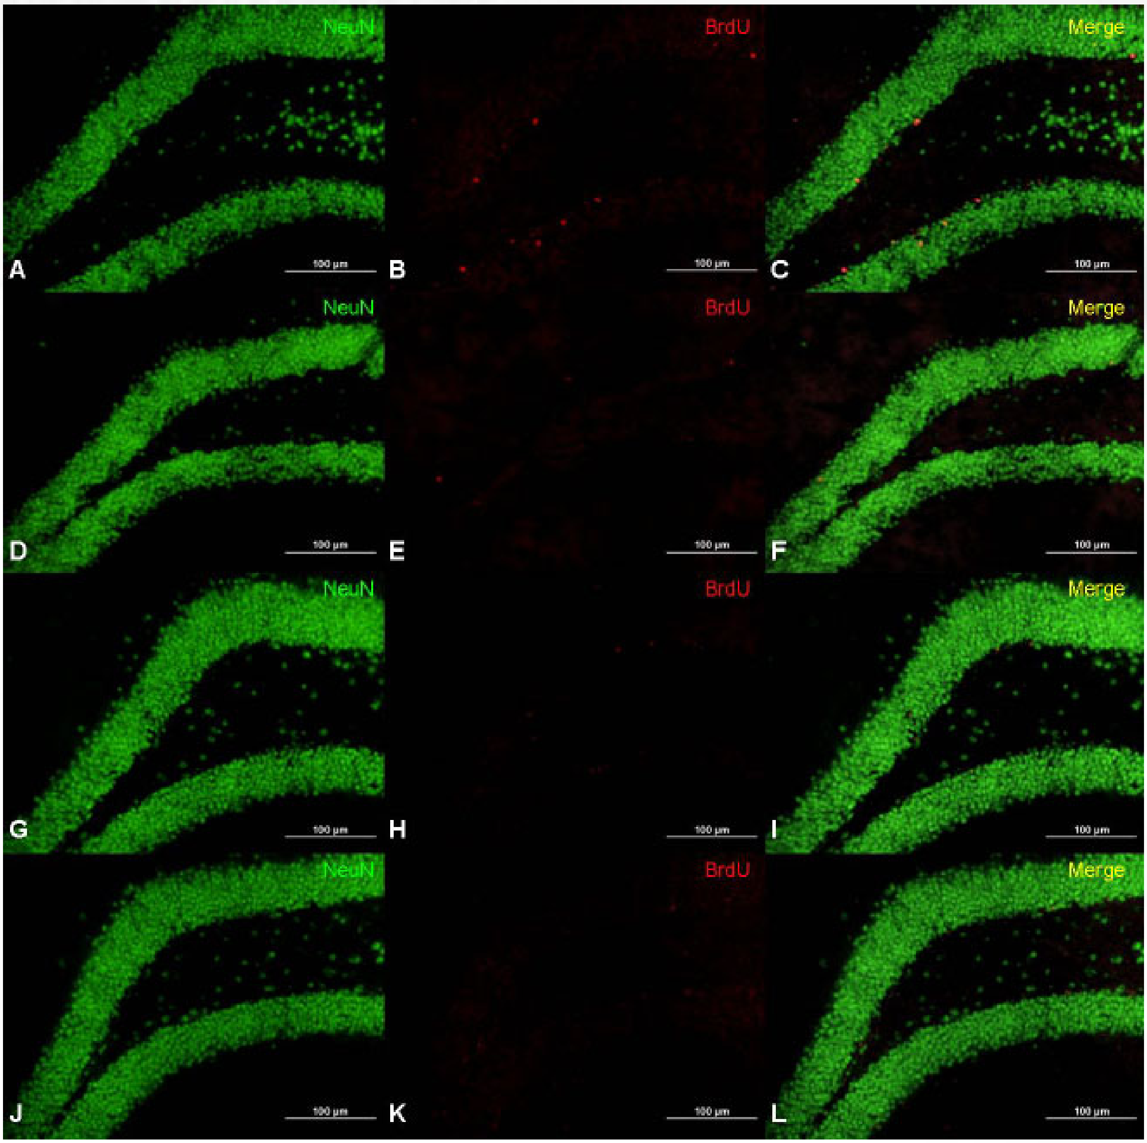

Figure 2.4. Representative photomicrographs showing the effects of the selective 5-HT_{2A} receptor agonist 251-NBMeO on hippocampal neurogenesis. NeuN+ cells (left), BrdU+ cells (center) and NeuN/BrdU+ cells (right). Saline (AC), 0.1 mg/kg 251-NBMeO (D-F), 0.3 mg/kg 251-NBMeO (G-I) and 1.0 mg/kg 251-NBMeO (J-L). Scale = 100 µM.

In addition, there was a significant effect of drug on the number of double labeled neurons in the DG [*F*(3,20)=3.00, *p*=0.03]. As can be seen in Figure 2.3B, 1.0 mg/kg 251-NBMeO significantly diminished the number of new born neurons in the DG compared to saline (*p*<0.05, indicated by *). These data suggest acute administration of the selective 5-HT$_{2A}$ receptor agonist, 251- NBMeO, attenuated hippocampal neurogenesis

Interestingly, acute administration of the 5-HT$_{2A/C}$ receptor antagonist ketanserin produced similar effects on neurogenesis as high doses of the 5-HT$_{2A}$ receptor agonists. As can be seen in figure 2.5, the total number of BrdU+ cells in the DG was significantly decreased after 1.0 mg/kg ketanserin [*t*(10)=3.0, *p*=0.008], suggesting that the 5-HT$_{2A/C}$ receptor is involved in the regulation of cell survival in the HPC. Furthermore, acute ketanserin decreased the total number of BrdU/NeuN positive cells compared to saline [*t*(10)=3.0, *p*=0.02] demonstrating that antagonism of the 5-HT$_{2A/C}$ receptor negatively regulated the number of new born neurons generated in the DG of the HPC.

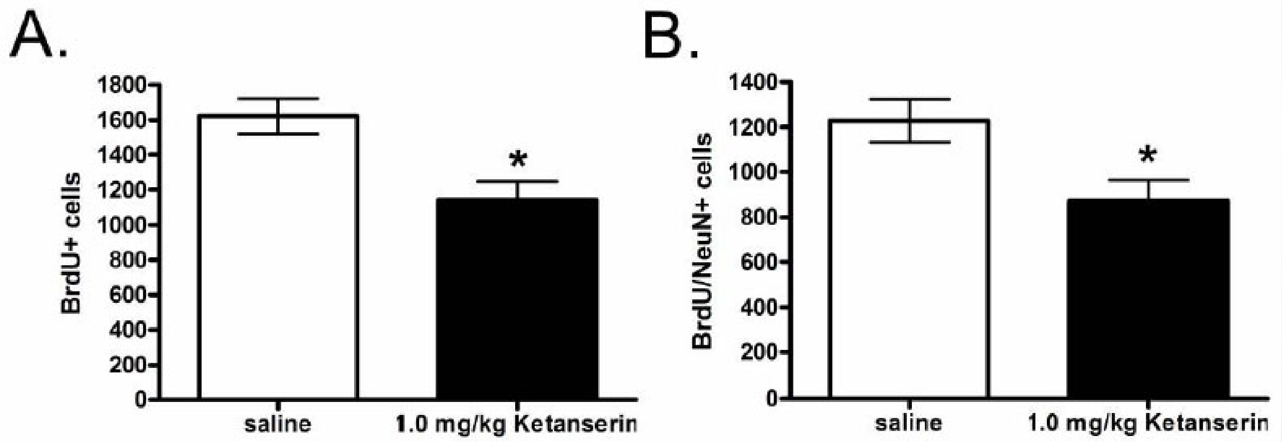

Figure 2.5. Acute Administration of the 5-HT$_{2A/C}$ receptor antagonist ketanserin negatively regulated cell survival and neurogenesis in the HPC. Mice (*n* = 6 per condition) were injected with 1.0 mg/kg ketanserin or saline then received 75 mg/kg BrdU once daily for 4 days following drug followed by euthanasia two weeks after drug injection. Ketanserin decreased the total number of BrdU+ (A) and BrdU/NeuN positive cells (B) suggesting that antagonism of the 5-HT$_{2A/C}$ receptor negatively regulated cell survival and neurogenesis in the HPC.

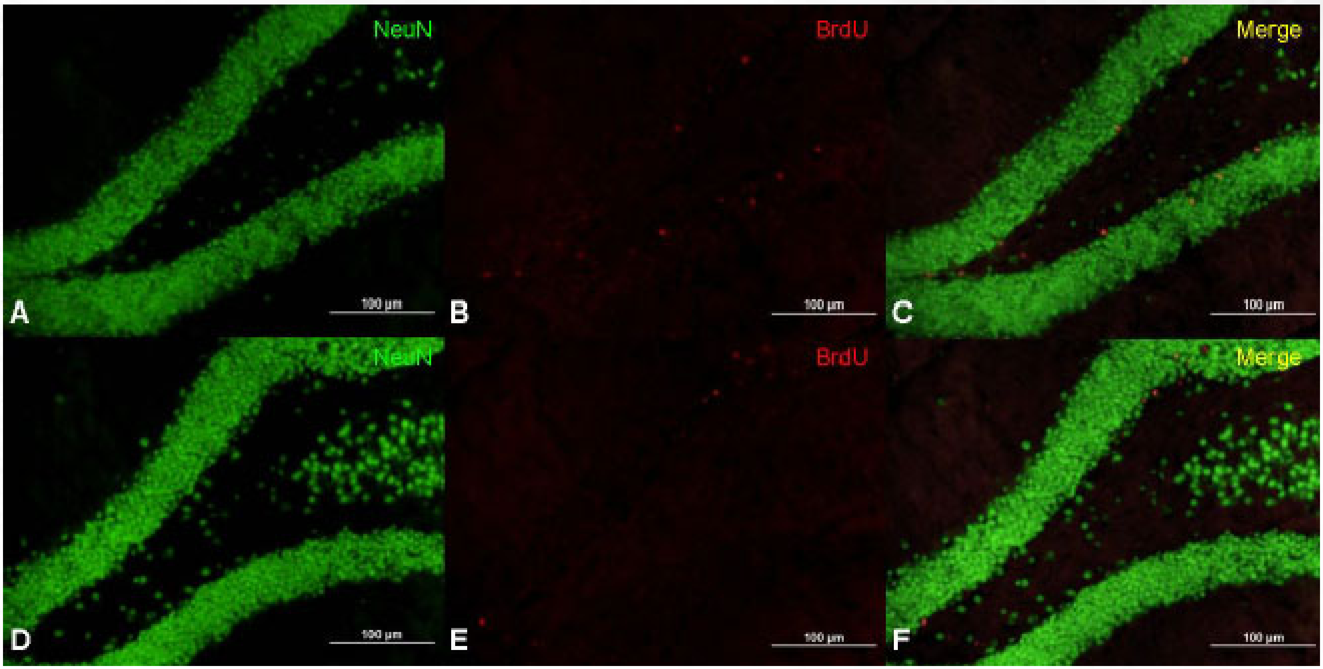

Figure 2.6. Representative photomicrographs showing the effects of the 5-HT$_{2A/C}$ receptor antagonist ketanserin on neurogenesis in the dentate gyrus. NeuN+ cells (left), BrdU+ cells (center) and NeuN/BrdU+ cells (right). Saline (A-C), 1.0 mg/kg ketanserin (D-F). Scale = 100 µM.

Effects of Repeated Intermittent PSOP Administration on Progenitor Cell Survival and Neurogenesis in the Hippocampus

In order to investigate the effects of repeated intermittent PSOP administration on cell survival mice (*n* = 6- 7 per condition) were injected with PSOP (0.5, 1.0, or 1.5 mg/kg), 1.0 mg/kg ketanserin or 0.9% saline solution once weekly for 4 weeks. Each day following drug administration, mice were administered 75 mg/kg BrdU and sacrificed two weeks after last drug injection. ANOVA failed to reveal differences in the total number of BrdU+ cells in the DG as a result of repeated intermittent drug treatment [$F(4,26)=2.20$, $p=0.09$]. As can be seen in Figure 2.7A a trend toward an increase in the number of surviving cells was observed after high doses of PSOP.

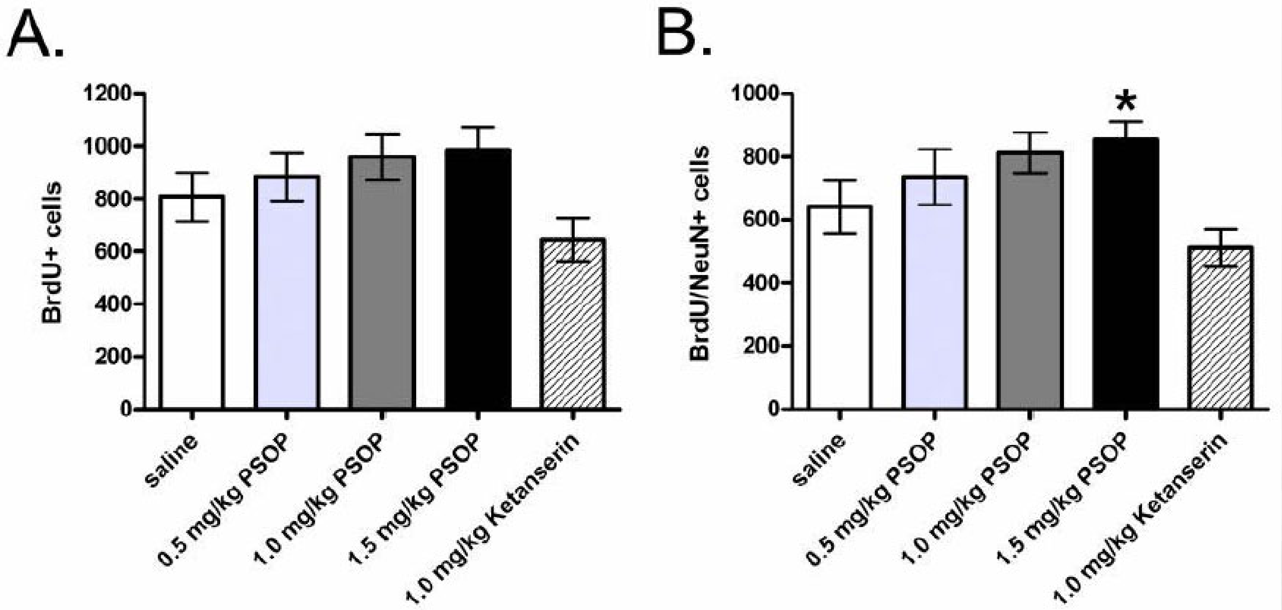

Figure 2.7. Effect of Repeated Intermittent PSOP Administration on Hippocampal Neurogenesis. Mice (*n* = 6-7 per condition) were injected with PSOP (0.5, 1.0, or 1.5 mg/kg), 1.0 mg/kg ketanserin or saline once weekly for 4 weeks. Each day following drug administration, mice were administered 75 mg/kg BrdU and sacrificed two weeks after last drug injection. A) The total number of BrdU+ cells in the DG did not differ as a result of repeated intermittent drug treatment, however, a trend toward an increase in the number of surviving cells was observed after high doses of PSOP. B) Repeated intermittent administration of 1.5 mg/kg PSOP significantly increased the number of BrdU/NeuN+ cells compared to saline and ketanserin ($p<0.05$). These data suggest repeated intermittent administration of high doses of PSOP, a 5-HT_{2A} agonist upregulated neurogenesis in the DG.
* indicates a significant difference from saline and ketanserin.

The phenotypic fate of surviving cells was determined by immunofluorescent labeling of BrdU and NeuN. ANOVA revealed a significant effect of Dose on the number of double labeled neurons in the DG [$F(4,26)=3.15$, $p=0.02$]. As can be seen in Figure 2.7B, chronic administration of 1.5 mg/kg PSOP significantly increased the number of BrdU/NeuN+ cells compared to saline and ketanserin ($p<0.05$) (indicated by *). These data suggest repeated intermittent administration of PSOP, a 5-HT_{2A} agonist upregulated neurogenesis in the DG of the HPC.

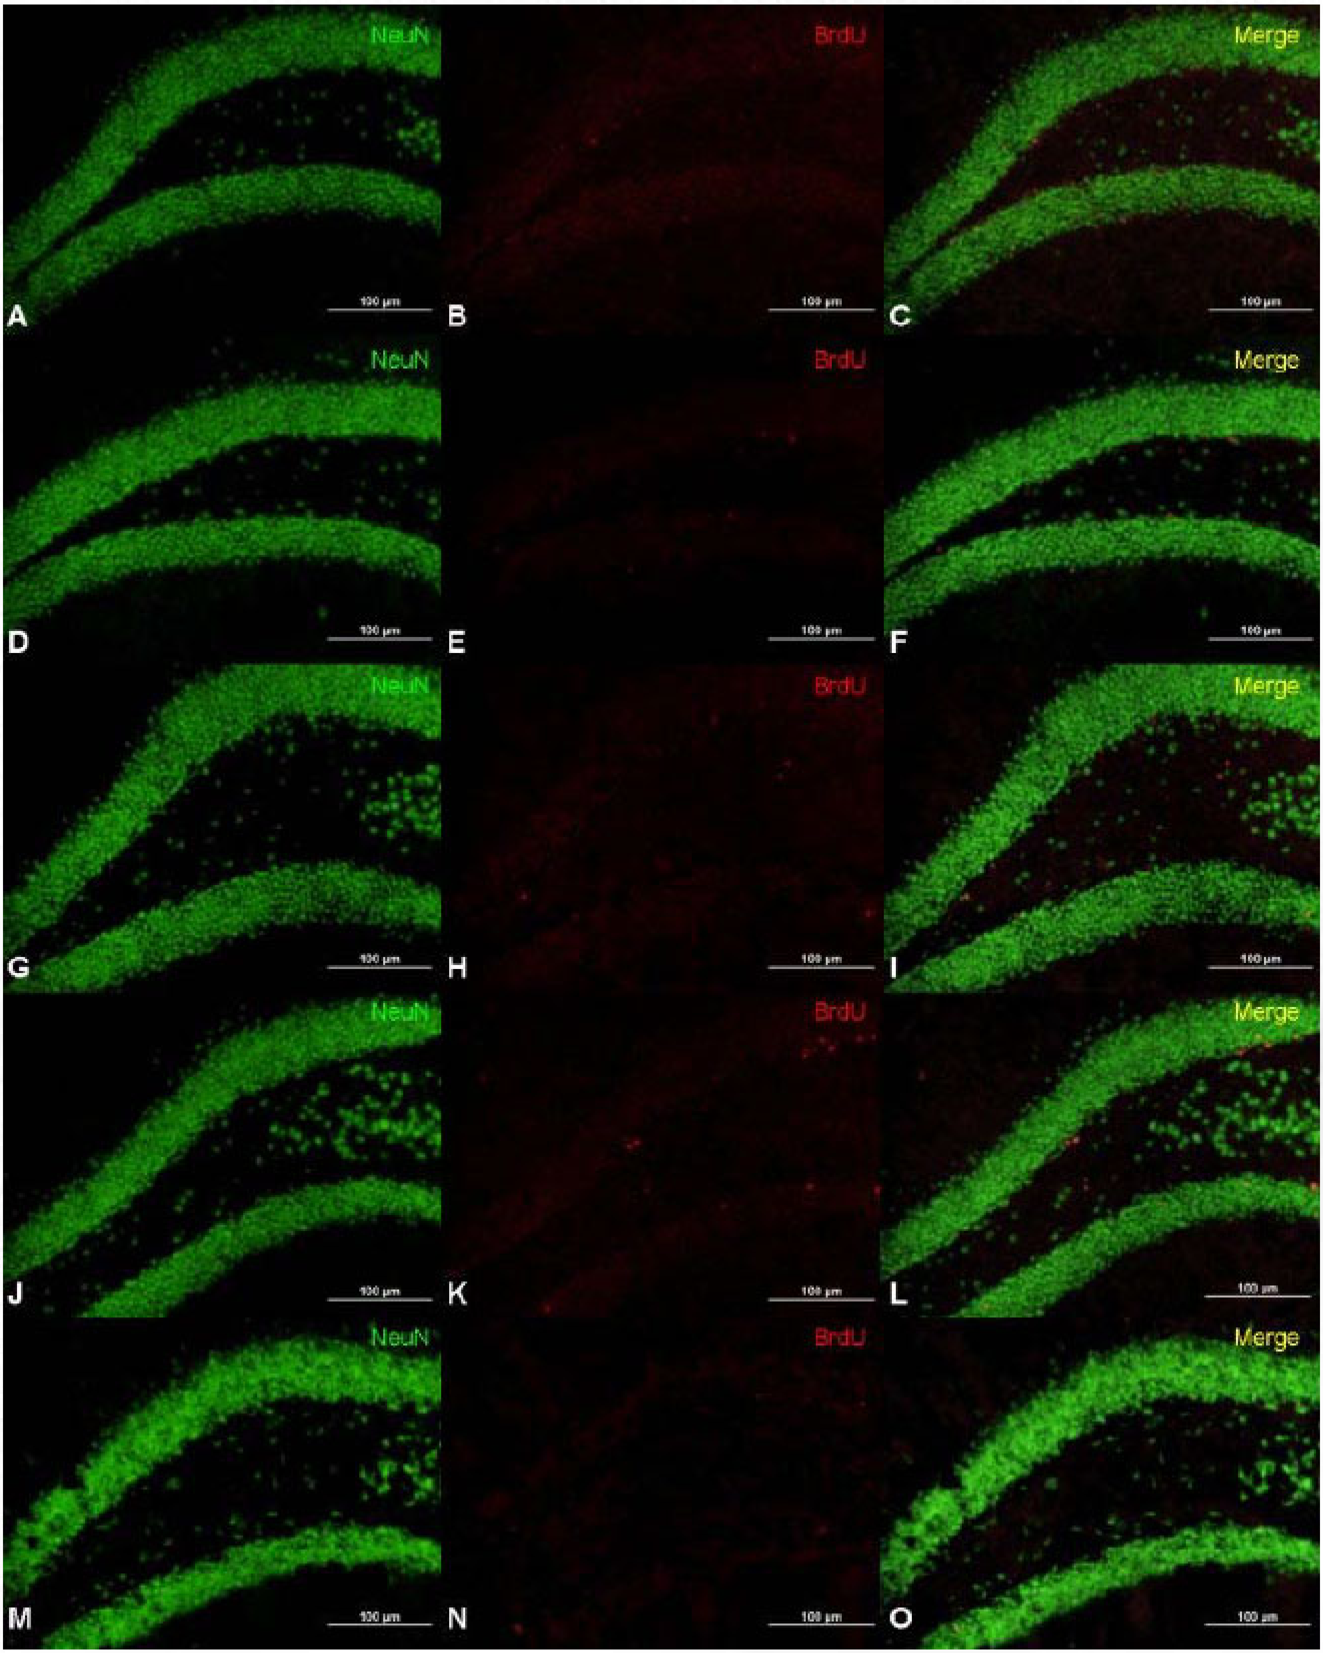

Figure 2.8. Representative photomicrographs showing the effects of repeated intermittent PSOP or ketanserin administration on neurogenesis in the DG. NeuN+ cells (left), BrdU+ cells (center) and NeuN/BrdU+ cells (right). Saline (AC), 0.5 mg/kg PSOP (D-F), 1.0 mg/kg PSOP (G-I), 1.5 mg/kg PSOP (J-L), and 1.0 mg/kg Ketanserin (M-O). Scale = 100 μM.

Discussion

The present investigation illustrates the involvement of the 5-HT$_{2A}$ receptor in the regulation of neurogenesis in the DG of the HPC. Acute administration of low doses of PSOP (0.1 and 0.5 mg/kg) did not alter neurogenesis, however, higher doses of PSOP (1.0 mg/kg) decreased neurogenesis two weeks after drug exposure (Figure 2.1). In addition, acute administration of the potent 5-HT$_{2A}$ receptor agonist 251-NBMeO (Figure 2.3) and the 5-HT$_{2A/C}$ receptor antagonist ketanserin (Figure 2.5) decreased hippocampal neurogenesis. Acute ketanserin (1-5 mg/kg) administered within 4 hours of sacrifice decreased the number of BrdU+ cells in the DG, indicating a reduction in cell proliferation (Banasr *et al.*, 2004; Jha *et al.*, 2008). The present study extends these findings by demonstrating that acute ketanserin decreases the number of BrdU+ and BrdU/NeuN+ cells 2 weeks after drug administration, indicating a reduction in cell survival and neurogenesis after exposure to acute ketanserin.

The current study reports that repeated intermittent administration of high doses of PSOP (1.5 mg/kg) increased neurogenesis in the DG (see Figure 2.7). A recent study investigated the effects of chronic DOI, LSD and ketanserin administration on the number of BrdU+ cells in the DG (Jha *et al.*, 2008). They report no effect of chronic DOI or LSD on progenitor cell proliferation but observed an increase in the number of BrdU+ cells in the DG after chronic ketanserin. There are several methodological differences between the studies which may account for the different results, namely drug administration protocol, doses of compounds administered and administration protocol of BrdU. Jha and colleagues administered DOI (8 mg/kg), LSD (0.5 mg/kg) or ketanserin (5 mg/kg) once daily for seven consecutive days for the chronic drug administration protocol (Jha *et al.*, 2008). The current investigation administered PSOP (0.5, 1.0 or 1.5 mg/kg) or ketanserin (1.0 mg/kg) 4 times over the course of one month so that injections were given one week apart. This was a critical consideration in our experimental design given that daily doses of LSD, PSOP or other 5-HT$_{2A}$ receptor agonists produce rapid tolerance to the drug and results in a selective downregulation of the 5-HT$_{2A}$ receptor (Buckholtz *et al.*, 1990; Buckholtz *et al.*, 1985; Buckholtz *et al.*, 1988). Jha and colleagues administered BrdU (200 mg/kg) 2 hours after the last injection of DOI, LSD or ketanserin and sacrificed the animals 24 hours later (Jha *et al.*, 2008). In the current study BrdU (75 mg/kg) was administered 24 hours after each drug injection and mice were sacrificed two weeks after the last drug injection so that time between the first BrdU injection and sacrifice was 6 weeks. This allowed for the assessment of neurogenesis giving time for the birth-dated cells (BrdU labeled) to mature into neurons.

Brain derived neurotropic factor (BDNF) has been implicated in synaptic plasticity (Kang *et al.*, 1997; Pang *et al.*, 2004; Tyler *et al.*, 2002) through the modulation of synapse formation and dendritic spine growth in the HPC (Bamji *et al.*, 2006; Tyler & Pozzo-Miller, 2001; Tyler & Pozzo-Miller, 2003). Chronic administration of 5-HT agonists (including SSRIs) upregulate BDNF mRNA expression in the HPC (Nibuya *et al.*, 1995; Nibuya *et al.*, 1996). Evidence suggests that the 5-HT$_{2A}$ receptor is involved in the regulation of BDNF in the HPC (Vaidya *et al.*, 1997). Specifically DOI, a 5-HT$_{2A/C}$ receptor agonist decreased BDNF mRNA expression in the granule cell layer of the DG but not in the CA subfields of the HPC. Interestingly, the decrease in BDNF mRNA expression was blocked by the 5-HT$_{2A}$ receptor antagonist but not the 5-HT$_{2C}$ receptor antagonist, implicating the 5-HT$_{2A}$ receptor in the regulation of BDNF expression (Vaidya *et al.*, 1997).

PSOP and 251-NBMeO exert their effects through binding to 5-HT receptors. PSOP binds to the 5-HT$_{2A}$ receptor (Ki = 6 nM) with high affinity and to a much lesser extent to the 5-HT$_{1A}$ receptor subtype (Ki = 190 nM) (McKenna *et al.*, 1990). The synthetic phenethylamine 251-NBMeO binds to 5-HT$_{2A}$ receptors (Ki = 0.044 nM) with an extremely high affinity (Braden *et al.*, 2006).

5-HT$_{2A}$ receptors are highly expressed throughout the HPC in the DG, hilus, CA1, and CA3 and are colocalized on GABAergic neurons, pyramidal and granular cells (Cornea-Hebert *et al.*, 1999; Morilak *et al.*, 1993; Pompeiano *et al.*, 1994; Shen & Andrade, 1998; Luttgen *et al.*, 2004; Morilak *et al.*, 1994). 5-HT$_{2A}$ receptor agonists stimulate arachidonic acid and consequently, the phosphoinositide (PI) pathway resulting in the activation of protein kinase C (PKC) (Kurrasch-Orbaugh *et al.*, 2003; Ananth *et al.*, 1987). Electrophysiological evidence suggests that 5-HT$_{2A}$ receptors stimulate GABAergic interneurons in the HPC (Shen & Andrade, 1998) and GABAergic interneurons in the hilus form connections with progenitor cells in the SGZ (Wang *et al.*, 2005). When progenitor cells are less than 2 weeks old the GABAergic input exerts an excitatory influence on the progenitor cells and as the cells establish glutamatergic synapses the GABAergic interneurons become inhibitory (Wang *et al.*, 2005; Zhao *et al.*, 2006; Aimone *et al.*, 2006). Given that 5-HT$_{2A}$ receptor agonists administered chronically downregulates receptor expression, and evidence suggests that the 5-HT$_{2A}$ receptor excites the GABAergic interneurons which stimulate progenitor cells in the SGZ, one might anticipate a reduction in neurogenesis after chronic PSOP. On the contrary, the present study reports high doses of PSOP upregulates neurogenesis. Based on this finding it is plausible to suggest the increase in neurogenesis observed may be attributed to the administration paradigm in which PSOP was given 4 times over the course of one month so that injections were given once a week. In this administration paradigm alterations in receptor levels may not have occurred to the extent that occurs with daily exposure and give this highly plastic microniche time to adapt between drug exposures.

The results shown provide evidence that the 5-HT$_{2A}$ receptor is involved in the regulation of hippocampal neurogenesis. The data suggest that acute administration of 5-HT$_{2A}$ receptor agonists and an antagonist downregulated neurogenesis in the DG. Whereas, chronic administration of high doses of 5-HT$_{2A}$ receptor agonists enhance hippocampal neurogenesis in the DG. Future studies should investigate the effects of chronic administration of PSOP and ketanserin on 5-HT$_{2A}$ receptor levels and neuroplasticity in the HPC.

Thanks to David Nichols Ph.D. for donating the selective 5-HT$_{2A}$ agonist 251-NBMeO and Dr Francisco Moreno from University of Arizona and Rick Doblin Ph.D. of the Multidisciplinary Association for Psychedelic Studies (MAPS) for donating the PSOP.

Chapter Three
The Effects of Psilocybin on Trace Fear Conditioning

Abstract

Aberrations in brain serotonin (5-HT) neurotransmission have been implicated in psychiatric disorders including anxiety, depression and deficits in learning and memory. Many of these disorders are treated with drugs which promote the availability of 5-HT in the synapse. However, it is not clear which of the 5-HT receptors are involved in behavioral improvements. The current study aimed to investigate the effects of psilocybin, a 5-HT$_{2A}$ receptor agonist on hippocampal-dependent learning. Mice received a single injection of psilocybin (0.1, 0.5, 1.0 or 1.5 mg/kg), ketanserin (a 5-HT$_{2A/C}$ antagonist) or saline 24 hours before habituation to the environment and subsequent training and testing on the fear conditioning task. Trace fear conditioning is a hippocampal-dependent task in which the presentation of the conditioned stimulus (CS, tone) is separated in time by a trace interval to the unconditioned stimulus (US, shock). All mice developed contextual and cued fear conditioning; however, mice treated with psilocybin extinguished the cued fear conditioning more rapidly than saline treated mice. Interestingly, mice given the 5-HT$_{2A/C}$ receptor antagonist ketanserin showed less of cued fear response than saline and psilocybin treated mice. Future studies should examine the temporal effects of acute and chronic psilocybin administration on hippocampal-dependent learning tasks.

Introduction

The hippocampus (HPC) plays a critical role in learning tasks that involve temporal encoding of stimuli (Squire *et al.*, 1992; Squire, 1992). The trace classical conditioning paradigm requires temporal processing because the conditioned stimulus (CS) and the unconditioned stimulus (US) are separated in time by a trace interval. Lesions to the HPC prevent trace conditioning, indicating that it is a hippocampal-dependent task (McEchron *et al.*, 1998; Weiss *et al.*, 1999).

The serotonergic system has been implicated in hippocampal-dependent learning. Administration of selective serotonin (5-HT) uptake inhibitors (SSRIs) produce alterations in performance on learning tasks that require the HPC (Flood & Cherkin, 1987; Huang *et al.*, 2004). In a knockout (KO) mouse model, central 5-HT deficient mice developed heightened contextual fear conditioning which was reversed by intracerebroventricular microinjection of 5-HT (Dai *et al.*, 2008). An impairment in learning on the morris water maze was observed in 5-HT$_{1A}$ KO mice along with functional abnormalities in the HPC (Sarnyai *et al.*, 2000). Activation of 5-HT$_{1A}$ receptors in the medial septum alters encoding and consolidation in a hippocampal-dependent memory task (Koenig *et al.*, 2008). In addition, Lysergic acid diethylamide (LSD), a 5-HT$_{2A}$ receptor agonist facilitated learning of a brightness discrimination reversal problem (King *et al.*, 1972; King *et al.*, 1974).

Evidence suggests that performance on hippocampal-dependent learning tasks is influenced by neurogenesis in the dentate gyrus (DG) of the HPC (Van *et al.*, 2002; Nilsson *et al.*, 1999; Shors *et al.*, 2001; Shors *et al.*, 2002; Gould *et al.*, 1999a; Gould *et al.*, 1999c). This was elegantly demonstrated by Shors and colleagues by treating animals with methylazoxymethanol acetate (MAM), an anti-mitotic agent which eradicates the progenitor cell population in the DG before testing mice on hippocampal-dependent and hippocampal-independent learning tasks (Shors *et al.*, 2001; Shors *et al.*, 2002). MAM treated animals had significantly fewer BrdU+ cells in the subgranular zone (SGZ) of the DG but showed no impairment in the spatial navigation task (HPC-dependent) or delay eyeblink conditioning task (HPC-independent) demonstrating that the hippocampal progenitor cell population is not essential for these particular tasks (Shors *et al.*, 2002; Shors *et al.*, 2001). In contrast, MAM severely impaired performance on trace fear conditioning and trace eyeblink conditioning, providing evidence for the involvement of progenitor cells in the DG in trace classical conditioning (Shors *et al.*, 2002; Shors *et al.*, 2001). In addition, hippocampal neurogenesis is influenced by serotonergic agonists. Specifically, SSRIs enhance the production of new born neurons in the DG of the HPC (Malberg *et al.*, 2000; Santarelli *et al.*, 2003).

Psilocybin (PSOP), a tryptamine alkaloid, exerts psychoactive effects by altering serotonergic neurotransmission (Passie *et al.*, 2002). PSOP binds to the 5-HT$_{2A}$ receptor (Ki = 6 nM) with high affinity and to a much lesser extent to the 5-HT$_{1A}$ receptor subtype (Ki = 190 nM) (McKenna *et al.*, 1990). 5-HT$_{2A}$ receptors are highly expressed throughout the HPC in the DG, hilus, CA1, and CA3 (Cornea-Hebert *et al.*, 1999; Morilak *et al.*, 1993; Pompeiano *et al.*, 1994; Shen & Andrade, 1998; Luttgen *et al.*, 2004; Morilak *et al.*, 1994). 5-HT$_{2A}$ receptor agonists, including PSOP, stimulate arachidonic acid (AA) and consequently, the phosphoinositide (PI) pathway resulting in the activation of protein kinase C (PKC) (Kurrasch-Orbaugh *et al.*, 2003; Ananth *et al.*, 1987). Electrophysiological evidence suggests that 5-HT$_{2A}$ receptors stimulate GABAergic interneurons in the HPC (Shen & Andrade, 1998) and GABAergic interneurons in the hilus form connections with progenitor cells in the SGZ (Wang *et al.*, 2005).

The present study aimed to investigate the effects of the 5-HT$_{2A}$ receptor agonist PSOP on hippocampal-dependent learning. Mice received a single injection of psilocybin (0.1, 0.5, 1.0 or 1.5 mg/kg), 1.0 mg/kg ketanserin (a 5-HT$_{2A/C}$ antagonist) or saline 24 hours before habituation to the environment and subsequent training and testing on the trace fear conditioning task.

Materials and Methods

Subjects

C57BL/6J male mice (30-40g) were housed in standard laboratory cages and left undisturbed for 1 week after arrival at the animal facility. All mice had unlimited access to water and laboratory chow and were maintained in a temperature and humidity controlled room on a 12:12 light/dark cycle with light onset at 7:00 AM. All National Institutes for Health (NIH) guidelines for the Care and Use of Laboratory Animals were followed (National Institutes of Health, 2002).

General Procedure

Mice (n=9-10/condition) received an intraperitoneal (i.p.) injection of PSOP (0.1 mg/kg, 0.5 mg/kg, 1.0 mg/kg, 1.5 mg/kg), ketanserin (1.0 mg/kg) or 0.9% saline and 24 h later were habituated to the testing chamber for 30 min. The fear conditioning environment consisted of two chambers each placed inside a larger soundproof chamber. The 35.6 (W) x 38.1 (D) x 31.8 (H) cm freeze monitor box (San Diego Instruments, San Diego, CA) is a clear Plexiglas chamber with a removable lid which contains a metal grid floor (0.3 cm grids spaced 0.8 cm apart) through which a foot shock can be delivered. Photobeam activity within the chamber recorded the vertical and horizontal movements of mice. Two minutes into the habituation period a baseline (BL) measure of movement was recorded for 3 minutes and served as the habituation BL measure. Freeze monitor boxes were cleaned with quatricide between each mouse to prevent olfactory cues. Mice were returned to their home cage after habituation.

The next day mice were returned to the same freeze monitor chamber and underwent training to form CS - US associations. After a 2 minute acclimation period, mice were exposed to 10 trials of trace fear conditioning which is illustrated in Figure 3.1. Each trial consisted of the CS (tone, 82 dB, 15 s) followed by a trace interval (30 s) and ended with the presentation of the US (shock, 0.5 s, 1 mA) delivered through the grid flooring. After each trial ended there was a 210 s intertrial interval (ITI). Freeze monitor boxes were cleaned with quatricide between each mouse to prevent olfactory cues and mice were returned to their home cage after training.

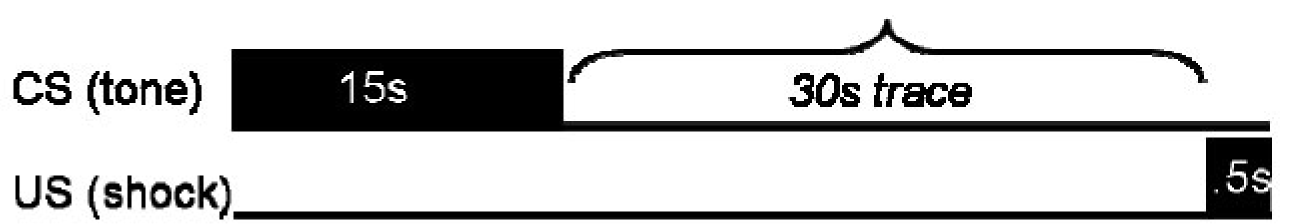

Figure 3.1. Schematic representation of the Trace Fear Conditioning Paradigm. Trace fear conditioning is a hippocampal-dependent task in which the presentation of the conditioned stimulus (CS, tone) is separated in time by a trace interval to the unconditioned stimulus (US, shock).

On day 3 of the task, testing of the fear conditioning response was assessed in 2 phases. First, mice were placed in the freeze monitor box for 5 minutes and movement was recorded for the last 3 minutes and used to assess the measure of fear associated to the training context. Mice were then returned to the home cage for 1 hour. Second, the context was altered by replacing the grid floors with black Plexiglas flooring and adding a cotton ball with 1ml vanilla essence inside the sound attenuated chamber. Mice were placed inside the novel chamber and after 2 minutes, movements were recorded for the next 3 minutes. Next 10 trials with the presentation of the CS only were delivered with an ITI of 240 s. Cue fear conditioning was measure by the percent freezing during the CS (tone; 15s), during the trace interval (30s) and after the trace when the US would have occurred. Conditioned fear was defined as an increase in percent immobility during the cue test. Percent immobility was calculated by dividing time spent immobile during stimuli (CS, trace or after trace) by the length of time the stimuli lasted multiplied by 100.

Design and analyses

Separate two-way repeated measure analyses of variance (ANOVA) were used to evaluate the effect of Dose and Trial on each dependent variable in the trace fear conditioning task. Dependent measures recorded included percent freezing during CS, during trace, after trace, during habituation BL, during the context test and in response to the novel environment. When appropriate, post hoc analyses such as Bonforreoni were used to isolate effects. All statistical analyses will be determined significant at the 0.05 alpha level.

Results

Acquisition

The acquisition of the freezing response is displayed in Figure 3.2 showing both the response to the CS (Figure 3.2A) and during the trace (Figure 3.2B). Using percent immobility in response to the CS for the first 3 trials of training, ANOVA showed that regardless of drug treatment there was a significant improvement across trial [$F(2, 108) = 40.0$, $p<0.0001$]. Specifically, immobility in response to the CS increased from trial 1 to trial 3 indicating the learned association between the stimuli during training ($p<0.05$). Additionally, ANOVA of the percent immobility during the trace interval revealed a significant effect of trial [$F(2, 108) = 20.0$, $p<0.0001$]. There was a striking increase in the amount of time spent immobile during the trace period from trial 1 to trial 3 demonstrating that the association between the CS and US promoted immobility in anticipation of the shock.

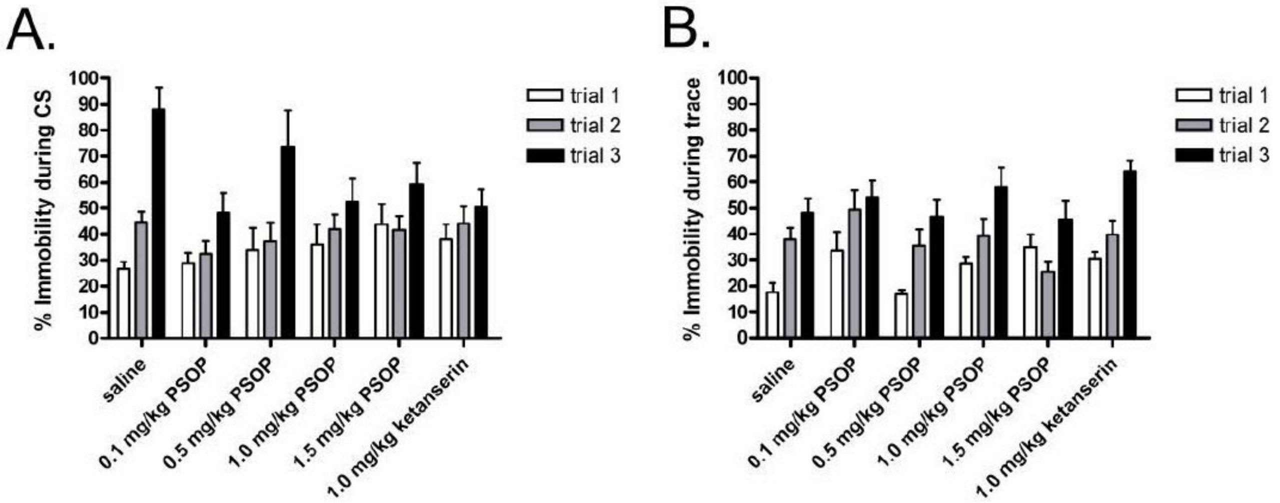

Figure 3.2. Effects of Psilocybin on the Acquisition of Trace Fear Conditioning. Mice underwent training to form CS - US associations by exposure to 10 trials of trace fear conditioning. Each trial consisted of the presentation of the CS (tone, 15-s) followed by a trace interval (30-s) and ended with the US (shock, 0.5-s). A) Percent immobility during presentation of the 15-s CS during the first three trials of CS - US pairing. B) Percent immobility during the 30-s trace interval during the first three trials of CS - US pairing.

Contextual Fear Conditioning

Contextual fear conditioning was assessed by comparing percent immobility in the freeze monitor box on habituation day to percent immobility during the context test. There was no interaction between Dose and Trial [$F(5,90) = 0.95$, $p=0.45$] and no effect of Dose during the habituation BL or context test [$F(5,90) = 1.15$, $p=0.34$]. However, there was a significant effect of Trial [$F(1,90) = 105.85$, $p<0.0001$] indicating that mice spent significantly more time freezing after the CS - US pairings during the context test compared to habituation BL. Figure 3.3 illustrates percent immobility during exposure to the freeze monitor box during the habituation test (A) and during the contextual fear conditioning test (B).

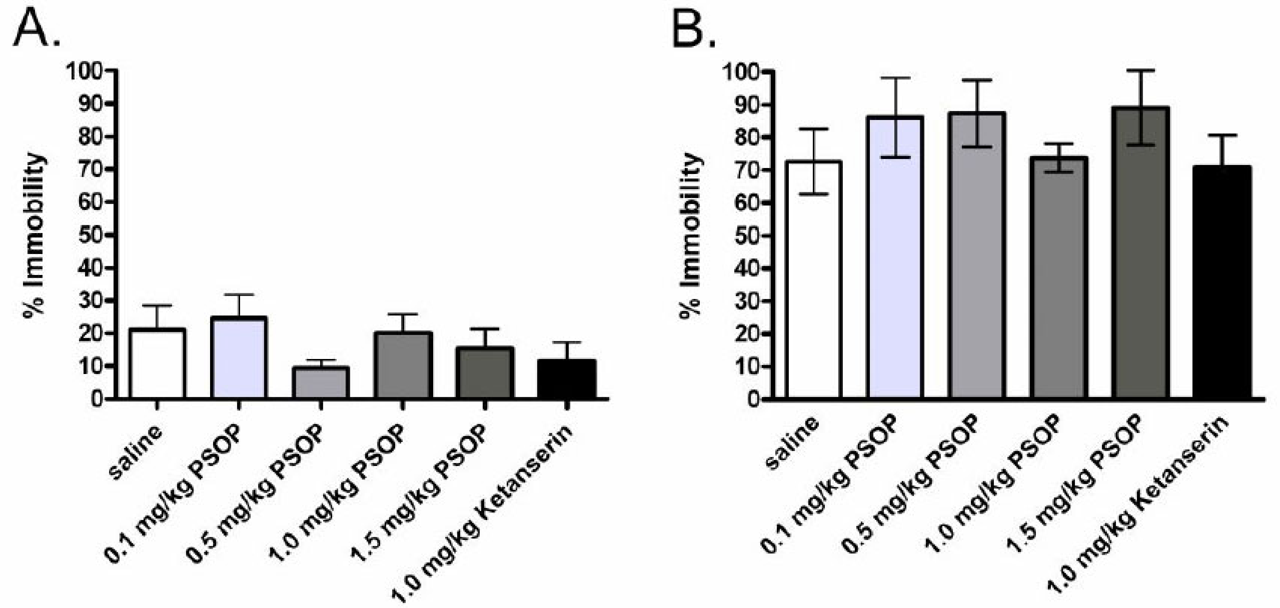

Figure 3.3. Contextual Fear Conditioning. Percent immobility expressed during exposure to the freeze monitor box during habituation (A) and during contextual fear conditioning (B). All mice expressed contextual fear conditioning as indicated by a significant increase in percent immobility during the context test ($p<0.05$).

Cue Fear Conditioning

Freezing responses (% immobility) during the CS only (tone) test are illustrated in Figure 3.4. There was a significant effect of Trial [$F(2,102) = 7.83$, $p<0.0007$] with trials 2 and 3 eliciting significantly more freezing in response to the CS compared to trial 1 (Figure 3.4A). There was also a significant effect of Dose [$F(5,51) = 4.96$, $p<0.0009$] revealing that control mice showed a greater fear response to the cue compared to 0.1 mg/kg

PSOP, 1.0 mg/kg PSOP, 1.5 mg/kg PSOP and 1.0 mg/kg ketanserin. ANOVA revealed a significant effect of Dose during the trace interval [$F(5,51) = 2.41$, $p<0.05$]. The fear associated with the trace interval during the first three trials on test day was reduced in mice treated with 1.0 mg/kg PSOP compared to saline and 1.5 mg/kg PSOP (Figure 3.4B). Figure 3.4C illustrates the fear response after the trace interval which coincides with the timing the US (shock) was delivered during the acquisition of the CS - US pairing phase. A two-way repeated measures ANOVA revealed a significant interaction between Dose and Trial [$F(10,100) = 3.53$, $p<0.0005$]. Interestingly, mice administered low doses of PSOP (0.1 and 0.5 mg/kg) froze more on trial 1 compared to trial 2 and 3 suggesting they are more apt to adapt to the absence of the US so that the fear response is diminished as the US is extinguished. This pattern was reversed in mice treated with ketanserin who increased fear responses from trials 1 to 3, indicating the robust memory for the US even in its absence. Taken together, these data suggest differential effects of PSOP on trace fear conditioning.

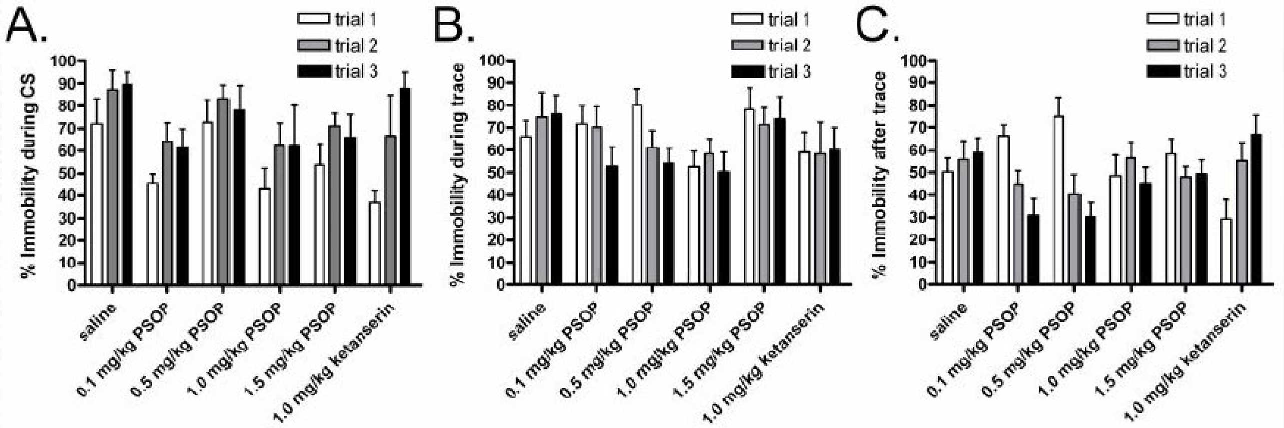

Figure 3.4. Effect of Acute PSOP on Cue Fear Conditioning. Cue fear conditioning was examined 24 hours after the training period in which mice were exposed to 10 trials of CS - US pairings. A) Percent immobility during presentation of the 15-s CS during the first three CS-only trials. B) Percent immobility during the 30-s trace interval during the first three trials. C) Percent immobility after the trace interval which coincides with the timing the US (shock) was delivered during the acquisition of the CS - US pairing phase.

Discussion

The present investigation illustrates the involvement of the 5-HT$_{2A}$ receptor in trace fear conditioning, a hippocampal-dependent learning task. During the acquisition of the freezing response there was a striking increase in the amount of time spent freezing during the presentation of the CS and during the trace period from trial 1 to trial 3 (see Figure 3.2). These data demonstrate that the association between the CS and US promoted freezing in anticipation of the shock, however, the acquisition of learning was not altered by acute administration of PSOP or ketanserin.

All conditions displayed similar locomotor activity levels in the freeze monitor box during the habituation baseline exposure and during re-exposure to the same environment during the contextual fear conditioning test. As expected mice froze substantially more during re-exposure to the same context after CS - US associations were formed compared to the habituation baseline, indicating that all groups formed contextual fear conditioning (Figure 3.3). It is well known that contextual fear conditioning is a hippocampal-dependent learning task (Kim & Fanselow, 1992; McNish *et al.*, 1997; Hirsh, 1974; Esclassan *et al.*, 2008; Frohardt *et al.*, 1999). The serotonergic system has been implicated in performance on the contextual fear conditioning task (Dai *et al.*, 2008). The present investigation found that the 5-HT$_{2A}$ receptor does not alter contextual fear conditioning since no differences were observed between controls and mice treated with PSOP or ketanserin.

The current study reports alterations in cue associated fear conditioning mediated by the 5-HT$_{2A}$ receptor. Independent of drug administered all mice developed cue-induced freezing during the presentation of the tone on the CSonly trial (see Figure 3.4). At the time coinciding with the expected US (shock) presentation low doses of PSOP (0.1 and 0.5 mg/kg) elicited a heightened freezing response on trial 1 compared to other trials suggesting they are more apt to adapt to the absence of the US so that the fear response is diminished as the US is extinguished. This pattern was reversed in mice treated with ketanserin who increased fear responses from trials 1 to 3, indicating the robust memory for the US even in its absence.

Synaptic plasticity in the HPC is critical for the acquisition of learning and memory. Brain derived neurotropic factor (BDNF) has been implicated in synaptic plasticity and memory processing (Kang *et al.*, 1997; Pang *et al.*, 2004; Tyler *et al.*, 2002) through the modulation of synapse formation and dendritic spine growth in the HPC (Bamji *et al.*, 2006; Tyler & Pozzo-Miller, 2001; Tyler & Pozzo-Miller, 2003). Chronic administration of 5-HT agonists (including SSRIs) upregulate BDNF mRNA expression in the HPC (Nibuya *et al.*, 1995; Nibuya *et al.*, 1996).

Evidence suggests that the 5-HT$_{2A}$ receptor is involved in the regulation of BDNF in the HPC (Vaidya *et al.*, 1997). Specifically DOI, a 5-HT$_{2A/C}$ receptor agonist decreased BDNF mRNA expression in the granule cell layer of the DG but not in the CA subfields of the HPC. Interestingly, the decrease in BDNF mRNA expression was blocked by the 5-HT$_{2A}$ receptor antagonist but not the 5-HT$_{2C}$ receptor antagonist, implicating the 5-HT$_{2A}$ receptor in the regulation of BDNF expression (Vaidya *et al.*, 1997).

5-HT$_{2A}$ receptors are highly expressed throughout the HPC in the DG, hilus, CA1, and CA3 and are colocalized on GABAergic neurons, pyramidal and granular cells (Cornea-Hebert *et al.*, 1999; Morilak *et al.*, 1993; Pompeiano *et al.*, 1994; Shen & Andrade, 1998; Luttgen *et al.*, 2004; Morilak *et al.*, 1994). Agonists to the 5-HT$_{2A}$ receptor stimulate AA and consequently, the PI pathway resulting in the activation of PKC (Kurrasch-Orbaugh *et al.*, 2003; Ananth *et al.*, 1987). Electrophysiological evidence suggests that 5-HT$_{2A}$ receptors stimulate GABAergic interneurons in the HPC (Shen & Andrade, 1998). Aberrations in GABAergic function in the HPC has been implicated in learning and memory due to the role of hippocampal GABA in temporospatial integration (Wallenstein *et al.*, 1998).

Taken together, the data reported in the present investigation implicate the 5-HT$_{2A}$ receptor in hippocampal-dependent learning. The present study reports that prior exposure to PSOP altered responsivity in a novel environment indicating an absence of a fear response, an effect not elicited by control mice. Furthermore, low doses of PSOP heightened cue elicited fear conditioning and antagonists to the 5-HT$_{2A/C}$ receptor diminished fear conditioning to the cue. Results of this study raise the possibility that 5-HT$_{2A}$ receptor activity could lead alterations hippocampal-dependent learning and memory.

Abstract

The psychological state elicited by the classic psychedelics drugs, such as LSD and psilocybin, is one of the most fascinating and yet least understood states of consciousness. However, with the advent of modern functional neuroimaging techniques, the effect of these drugs on neural activity is now being revealed, although many of the varied phenomenological features of the psychedelic state remain challenging to explain. Integrated information theory (IIT) is one of the foremost contemporary theories of consciousness, providing a mathematical formalization of both the quantity and quality of conscious experience. This theory can be applied to all known states of consciousness, including the psychedelic state. Using the results of functional neuroimaging data on the psychedelic state, the effects of psychedelic drugs on both the level and structure of consciousness can be explained in terms of the conceptual framework of IIT. This new IIT-based model of the psychedelic state provides an explanation for many of its phenomenological features, including unconstrained cognition, alterations in the structure and meaning of concepts and a sense of expanded awareness. This model also suggests that whilst cognitive flexibility, creativity, and imagination are enhanced during the psychedelic state, this occurs at the expense of cause-effect information, as well as degrading the brain's ability to organize, categorize, and differentiate the constituents of conscious experience. Furthermore, the model generates specific predictions that can be tested using a combination of functional imaging techniques, as has been applied to the study of levels of consciousness during anesthesia and following brain injury.

Keywords: integrated information theory, psychedelic state, psilocybin, ketamine, LSD, neural complexity, integration, neural entropy

Introduction

The psychological state elicited by the classic psychedelics drugs, such as LSD and psilocybin, is one of the most fascinating and yet least understood states of consciousness. Although biochemical and pharmacological studies of these drugs are detailed and extensive (Nichols, 2004), until recently, studies using human subjects have been limited. However, with the advent of modern functional neuroimaging techniques and the successful maneuvering around mulish political obstacles, the neural correlates of the psychedelic state in humans are now being revealed. This has prompted the development of new models of the effects of these drugs on neural function and their relationship to the phenomenological features of the psychedelic state (Vollenweider *et al*., 1997; Carhart-Harris *et al*., 2012, 2014).

Integrated information theory (IIT) is one of the foremost contemporary theories of consciousness (Oizumi *et al*., 2014). By mathematically formalizing the properties of subjective consciousness self-evident to humans, IIT attempts to explain the conditions under which systems, such as the brain, are conscious and for the phenomenological structure of conscious experience. Although IIT is continually under development, it is now a mature and rigorous theory that considers both the quantity and quality of consciousness in all its usual states, including waking, REM, and NREM sleep, during seizures and under anesthesia. As such, it would be extremely surprising if IIT had nothing to inform us about the nature of the psychedelic state. As we appear to be within a growing resurgence of psychedelic research in humans, it seems entirely appropriate and timely to analyze the psychedelic state from the perspective of IIT, with the aim of providing fresh insights into this beguiling state of consciousness. Furthermore, the mathematical rigor with which IIT is constructed might allow any such insights to be similarly formalized, perhaps pointing toward a more quantitative measure of the psychedelic state and an explanation for the range of effects of different psychedelic drugs. Importantly, the most recent models of the psychedelic state, developed based on functional imaging data (Carhart-Harris *et al*., 2014), will be shown not only to be compatible with IIT, but complemented by it. This analysis will also generate testable predictions regarding phenomenological features of the psychedelic state and its neural correlates, and suggest specific experiments to guide further research.

Phenomenology of the Psychedelic State

The effects of psychedelic drugs on consciousness, particularly at higher doses, can be both profound and varied (Masters, 1966). However, the effects can loosely be placed into three categories:

> Perceptual effects: altered shapes and colors (often appearing brighter, more vivid, and intense); visual distortions; visual hallucinations (open eye visuals and closed eye visuals); illusions; difficulty focusing; synaesthesias.
>
> Psychic effects: mood alterations (from ecstatic euphoria to panic); time distortion; thought alterations (difficulty concentrating, strange concepts, ideas, or connections, increases in creativity); dreamlike feelings; depersonalization; the sense that awareness is "expanded".
>
> Somatic effects: dizziness; tremors; nausea; drowsiness; blurred vision. (Masters, 1966; Hollister, 1984; Nichols, 2004).

The relative prominence of particular effects can be strongly dependent on the specific drug, the dosage and the setting in which the drug is used. As such, it is beyond the scope of this discussion to attempt an explanation for all the varying phenomenological features of the psychedelic state elicited by different psychedelic drugs. However, recent functional imaging studies suggest that, at relatively low doses of the classic psychedelic psilocybin, the psychedelic state is characterized by an unconstrained form of cognition (Carhart-Harris *et al.*, 2012, 2013; Roseman *et al.*, 2014); the stream of conscious experience appears more fluid and dynamic, with novel neural states being explored (Tagliazucchi *et al.*, 2014). It is straightforward to extrapolate this data to account for many of the perceptual and psychic effects that often manifest in the psychedelic state, although a more thorough and definitive treatment must await further human studies.

Functional Neuroimaging of the Psychedelic State

The classic psychedelic drugs are all partial agonists at the serotonin 5-HT$_{2A}$ receptor, and this site has been established as the major locus for their effects (Vollenweider *et al.*, 1998; Nichols, 2004). The earliest functional imaging studies suggested that psychedelic drugs, psilocybin specifically, are cortical activators and this was deemed to be consistent with the rich, heightened state of awareness characteristic of the psychedelic state (Vollenweider *et al.*, 1997). Further, activation of 5-HT$_{2A}$ receptors is known to depolarize cortical pyramidal neurons. As such, it was something of a surprise, and ostensibly paradoxical, when a groundbreaking functional magnetic resonance imaging (fMRI) study with psilocybin revealed a global decrease in cortical activation (Carhart-Harris *et al.*, 2012). However, recent magnetoencephalography (MEG) studies localized the activated pyramidal neurons to the deep layer V of the cortex, which provide predominantly inhibitory feedback, explaining why activation of this neural population results in a decrease in neural activity (Muthukumaraswamy *et al.*, 2013). The conflict with earlier data has been explained as an effect of the difference in temporal resolution between positron emission tomography (PET) and fMRI. It should be noted that, from the perspective of IIT, neural activation holds no primacy over deactivation, as both can be equally informative.

Maximal decreases in activation were observed in cortical "hubs," such as the anterior and posterior cingulate cortices (ACC and PCC) and the thalamus, as well as the medial prefrontal cortex (mPFC). Further, the intensity of the subjective effects of the drugs correlated with the magnitude of this deactivation (Carhart-Harris *et al.*, 2012). Functional connectivity analysis revealed an uncoupling of activity between the mPFC and the PCC, both key components of the default mode network (DMN), indicating a loss of network integrity (Carhart-Harris *et al.*, 2013; Muthukumaraswamy *et al.*, 2013). The DMN, also known as the task negative network (TNN), is preferentially activated during introspection, daydreaming and memory retrieval (Qin and Northoff, 2011). Activation of this network is normally anti-correlated (inversely coupled) with activation of task positive networks (TPNs) (Fox *et al.*, 2005), which are activated during attention-demanding tasks, such as attending to external visual stimuli. However, both fMRI and MEG revealed a decrease in the anti-correlation between the DMN and several TPNs, with an increase in the functional connectivity between these networks post-psilocybin. Overall, this functional imaging data indicates that psilocybin reduces the differentiation between brain networks and produces a "disorganized" brain state. This prompted Carhart-Harris and colleagues to propose that the psychedelic state is characterized by elevated neural entropy - the so-called "entropic brain" theory (Carhart-Harris *et al.*, 2014).

According to this model, during normal waking consciousness, the brain operates at a slightly subcritical state between a highly ordered, low entropy (sub-critical) state and a highly disordered, high entropy (super-critical) one (Chialvo, 2010). This optimal position between perfect order and complete disorder allows the brain to operate in a well-defined and organized manner whilst maintaining a degree of pliability, which is essential for flexible and adaptable cognition. Psychedelic drugs, such as psilocybin, increase the entropy of the brain and generate a more disordered and fluid state of consciousness, as revealed by the functional connectivity analyses. Further, more targeted analyses of the psilocybin fMRI data showed an increase in the variance of neural activation across voxels within networks associated with higher cognition, indicative of more erratic neural activity. A formal measure of Shannon entropy was also employed and, in line with the predictions of the entropic brain theory, entropy was indeed elevated in these networks (Carhart-Harris *et al.*, 2014).

A related approach was used to examine the entropy of the dynamic temporal sequence of states (discretized as functional connectivity motifs) explored by the brain post-psilocybin. Crucially, this analysis not only revealed that the sequence of states was more random (higher entropy) post-psilocybin, but also that specific connectivity motifs were exclusive to the psilocybin state (Carhart-Harris *et al.*, 2014; Tagliazucchi *et al.*, 2014). This indicates that psilocybin increases both the entropy of the brain and the size of its state repertoire, which will be of central importance when considering the psychedelic state from the perspective of IIT.

Overview of Integrated Information Theory (IIT)

Before examining the psychedelic state from the perspective of IIT, it is essential that the key ideas of IIT be presented, particularly those that will be used in the sections that follow. However, it is not the aim of this section to provide a detailed and thorough account of IIT and the reader is directed to Giulio Tononi's papers explaining the theory (Oizumi *et al.*, 2014). This section will serve merely as a simplified overview of IIT, with particular emphasis placed on those aspects of the theory most informative to the psychedelic state.

IIT provides a formal description of both the quantity of consciousness and its quality (structure), both of which might be affected by psychedelic drugs. In order for a system to be conscious, it must be both highly differentiated (informative) and integrated. This means the information generated by the system as a whole must be beyond that generated by its individual components. That is, it must be irreducible. IIT proposes that a set of neural elements (e.g., thalamocortical columns) with the special property of being a local maximum of integrated information, quantified by Φ (big phi), is conscious. This set of neural elements is known as a *maximally irreducible conceptual structure* (also known as a *complex*). Only a complex exists from its own perspective (there is *something-it-is-like-to-be it* Nagel, 1974). All conceptual structures, whether maximally irreducible or not, are defined as systems of *concepts*. Although a concept has a formal definition in IIT, this is simply a formalization of the more familiar definition: an abstract idea or an object of thought consisting of all the essential or characteristic features of that object. This could refer to a concrete object, such as an apple or a chair, but might also refer to something more abstract, such as the color red or the concept of freedom or happiness. As concept theory is a major branch of both classical and contemporary philosophy, it is perhaps safest to opt for the simplest definition - "concepts are the constituents of thoughts" (Margolis and Laurence, 2014), although "constituents of conscious experience" is perhaps a more helpful definition here.

As conscious experience is built as a system of concepts, understanding the definition of a concept is central to understanding how IIT describes the structure of consciousness and how psychedelic drugs can change it. Assuming the cortical column is chosen as the basic unit of functional segregation, each column is an *element* of the *system* under consideration (e.g., a region of the cerebral cortex). Elements can be combined with other elements to form *mechanisms* (e.g., a set of directly or indirectly connected cortical columns engaging in some sort of causal interaction) (**Figure 1**).

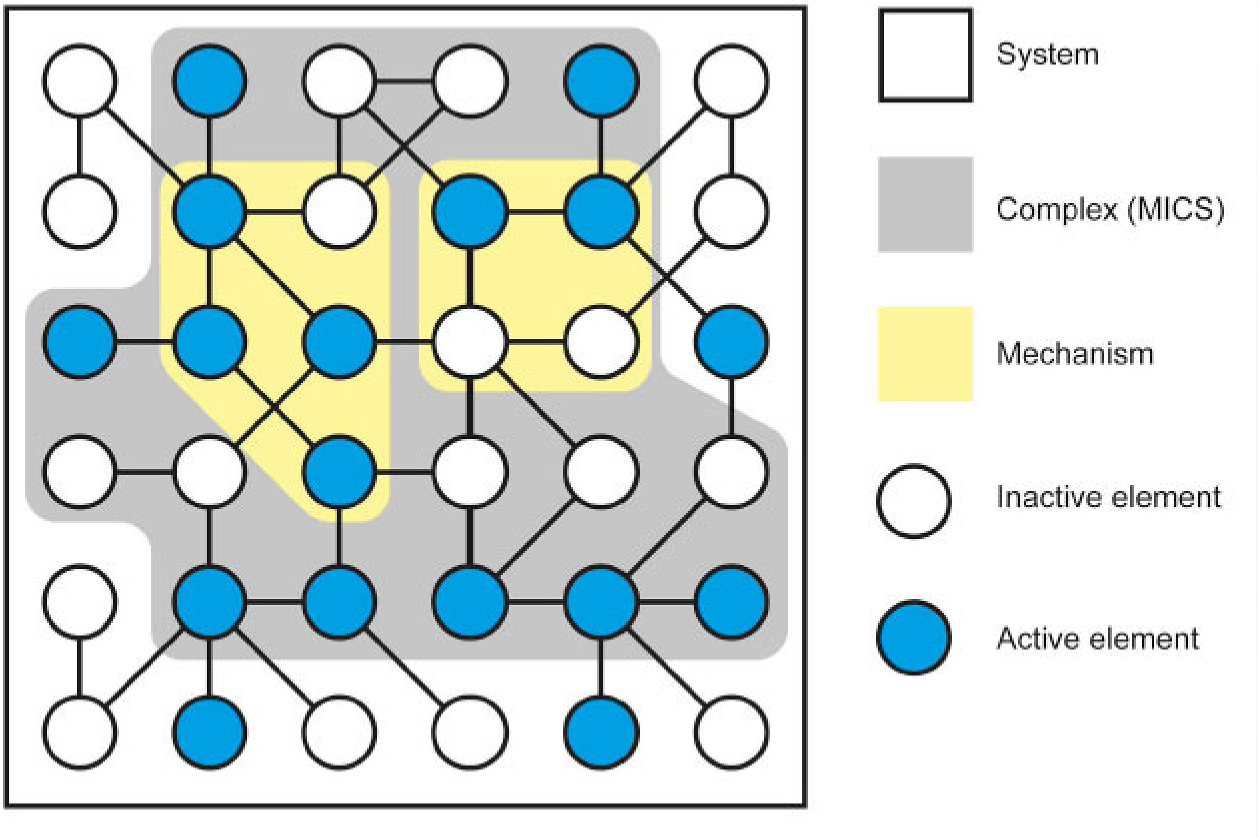

FIGURE 1 - Neural elements within the system form mechanisms (only 2 mechanisms within the power set are shown). The particular current state of the mechanism is defined by the activity or silence of individual neural elements and determined by their causal interactions. The complex comprises the set of neural elements in the system that forms a maximally irreducible conceptual structure (MICS).

The element itself is the most elementary mechanism and elements can combine to form higher order mechanisms. For any set of elements, all possible mechanisms are represented as the *power set*, which includes all possible combinations of elements, including the highest order mechanism, which is the set itself. Dependent on the interactions between the elements of the mechanism and, in fact, with the elements of the entire system (in the case of the brain, the synaptic connections, their type, and weight, etc.), every mechanism occupies a particular state at any point in time (hereafter its *current state*). For example, particular sets of neurons might be firing, whilst others are quiet. As the system consists of causal, deterministic interactions, only certain system states could have *caused* the mechanism to enter its current state. This set of system states is a discrete probability distribution called the *cause repertoire* (IIT uses the term *repertoire* to describe various discrete distributions of system states). Likewise, given the current state of the mechanism, only a specific set of immediate future states will be available to the system - this is the *effect repertoire*. Both of these repertoires may be referred to together as the *cause-effect repertoire* (**Figure 2**). So, by entering its current state, a mechanism *constrains* both the past and future states of the system. In actuality, each individual mechanism may not constrain the past and future states of the entire system, but rather of a specific subset of elements called the *purview*. Any elements outside of the purview are unconstrained by the mechanism. However, all of the mechanisms together will constrain the past and future states of the entire system.

Prior to considering the current state of any mechanisms, all the possible past and future states of the system form the maximal entropy *unconstrained past and future repertoires*, respectively (i.e., unconstrained by any mechanisms in any specific state). By entering a specific current state, a mechanism effectively rules out certain past and future system states (i.e., those past states that could not have caused the current state and those immediate future states that cannot follow) and thus generates information. The amount of information the mechanism specifies about the past state of the system is called the *cause information* and is obtained by calculating the [Earth Mover's] distance between the *cause repertoire* and the *unconstrained past repertoire*. The larger the difference between these distributions, the more the current state of the mechanism constrains the past states of the system and thus the more cause information is generated. If the cause information is zero (i.e., there is no difference between the distributions), the current state of the mechanism tells us nothing about the past state of the system. Likewise, the distance between the *effect repertoire* and the *unconstrained future repertoire* quantifies the *effect information*. The minimum of the cause and effect information is the *cause-effect information* (**Figure 2**). By systematically bipartitioning the mechanism, it is possible to calculate the *cause-effect information* specified by the whole mechanism above and beyond that specified by its parts. This is the integrated information specified by the mechanism and is known as φ (small phi). Overall, the elements of the mechanism, together with its cause-effect repertoire and associated value of φ, constitute a concept (Figure 3A). *The states of the cause-effect repertoire specify what the concept "is about" and φ quantifies the degree to which that concept is present within the conscious experience of the system*. Every possible mechanism may, in principle, specify a concept. However, if the mechanism fails to generate any integrated information (i.e., if φ = 0), then the concept does not exist from the subjective perspective of the complex (i.e., it is not present within the conscious experience).

Past system states ruled out by current state of mechanism
Future system states ruled out by current state of mechanism
Cause-Effect Repertoire, CER
Concept = (CER, φ^{MAX})
Cause-Effect Information (CEI) = min(CI,EI) = φ^{MAX} (assuming maximally irreducible)
D = Earth Mover's Distance (Wasserstein Metric)

FIGURE 2 - **The current state of a mechanism is associated with a specific cause-effect repertoire of past and future states of the system.** The mechanism generates information by ruling out certain past and future states, quantified as the distance between the cause-effect repertoire and the unconstrained past-future repertoire.

Of all the concepts specified by the system, subsets of these can form *conceptual structures*, with each concept represented as a point in *concept space*, a high-dimensional space in which each possible past and future state within the cause-effect repertoire is represented by one dimension (axis). The coordinates of the point are given by the probabilities of each past and future state in the cause-effect repertoire and φ is represented by the size of the point. A conceptual structure thus forms a constellation of points in concept space (**Figure 3B**). Whilst each concept specifies a quantifiable amount of cause-effect information, a conceptual structure generates *conceptual information*, which is the systems equivalent of cause-effect information. The conceptual

)

information of each concept is found by calculating the difference between the cause-effect repertoire of the concept and the unconstrained cause-effect repertoire (known as the *null concept*, a concept about nothing). This difference is then multiplied by the φ-value of the concept. Summing over all the concepts gives the conceptual information generated by the conceptual structure, denoted Φ (big phi). Clearly, a conceptual structure with many high-φ concepts that are well-separated from the null concept will generate a large amount of conceptual information. Conversely, a poorly integrated system with a limited repertoire of states will generate only a small amount of conceptual information (Oizumi *et al*., 2014).

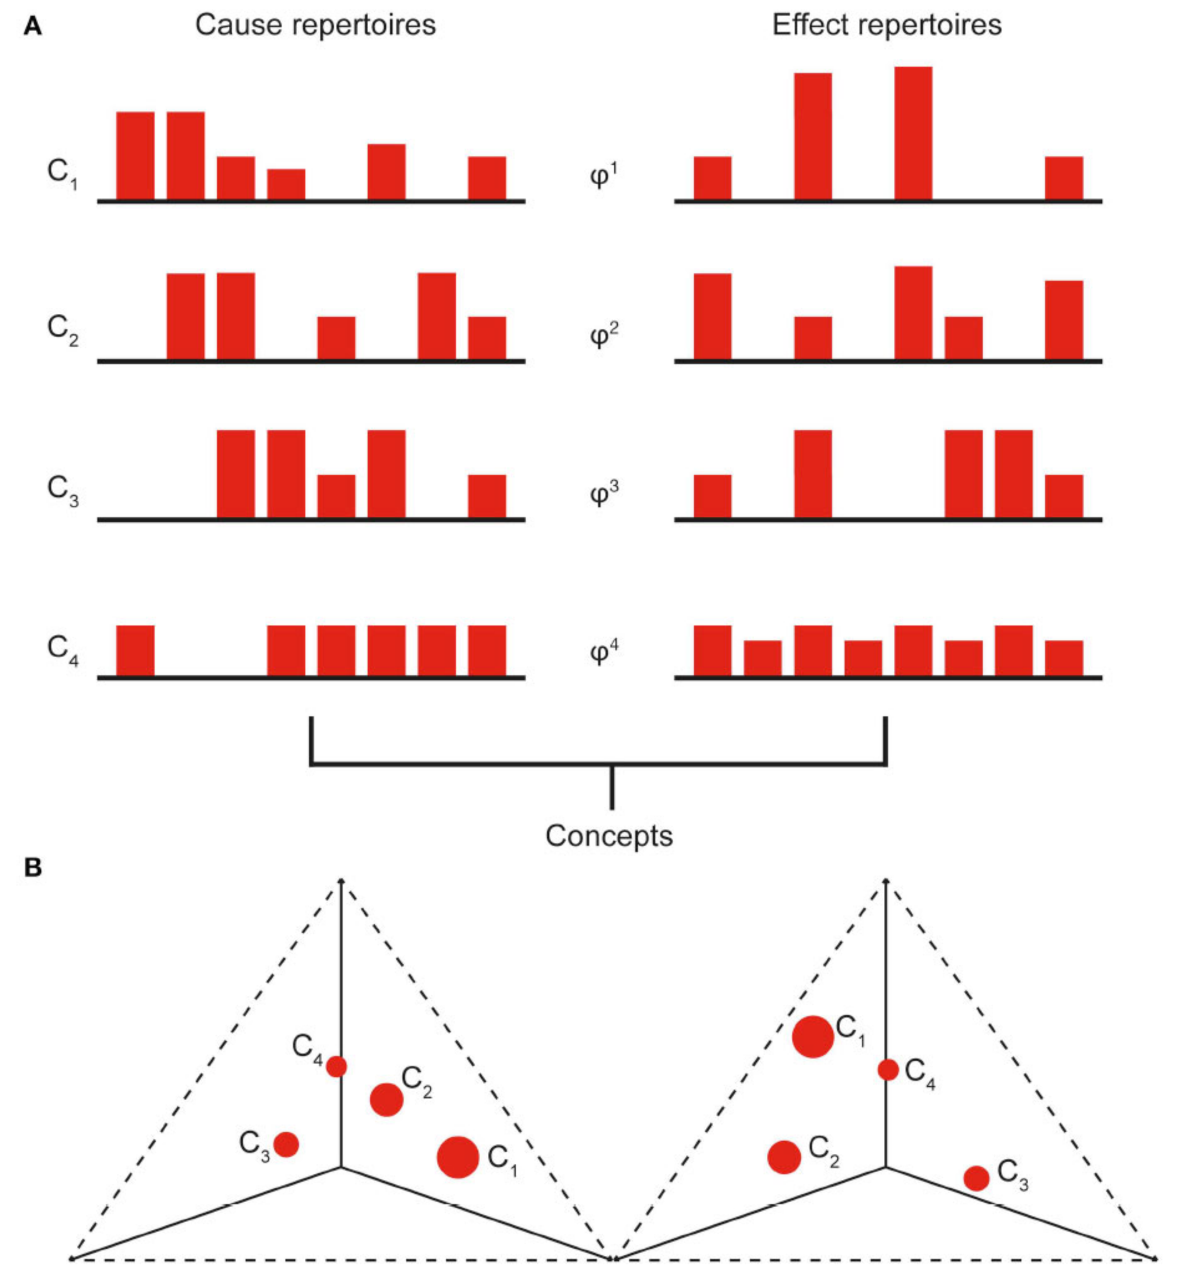

FIGURE 3 - **(A)** The cause-effect repertoire of each mechanism within a complex, together with its associated φ value, constitutes a concept. The states of the cause-effect repertoire define what the concept "is about" and φ quantifies the degree to which the concept is present in the experience. **(B)** Concept (qualia) space is a high-dimensional space with each cause-effect repertoire state occupying a single axis. Plotting the concepts on these axes, the conceptual structure forms a shape in this space that is identified with the conscious experience (qualia). (Only 3 axes shown with past and future states plotted on separate axes).

In principle, any subset of concepts within the power set of concepts specified by the system can form a conceptual structure. However, only one conceptual structure can exist at any time from the intrinsic perspective of the system - this is the MICS (complex), which specifies the maximal amount of integrated conceptual information (Φmax, hereafter simply Φ). Not all concepts with non-zero φ will form part of this irreducible conceptual structure. This is intuitively obvious, as conscious experience changes from moment to moment, as concepts continuously enter and leave consciousness. Concepts that leave the complex cease to exist from the subjective perspective of the complex, but may re-enter the complex at a later time.

The subjective conscious experience of the complex is identified with the complex itself - the level or quantity of consciousness is identified with the value of Φ, whereas the constellation of concepts determines the structure or quality of the experience (quale) (**Figure 4**). Each concept contributes to the overall experience, with its cause-effect repertoire determining what that concept "is about" and its φ-value quantifying the degree to which the concept is present in the experience. Each concept is a point in a high-dimensional *qualia space* (this is the same as concept space, except only complexes (MICS) have qualia) and thus the constellation of concepts form a "shape" in this space (Balduzzi and Tononi, 2009). It is this shape that is identified with the quality of the experience. The higher the dimensionality of the qualia space, the richer the experience (i.e., the experience is "about more things" at once).

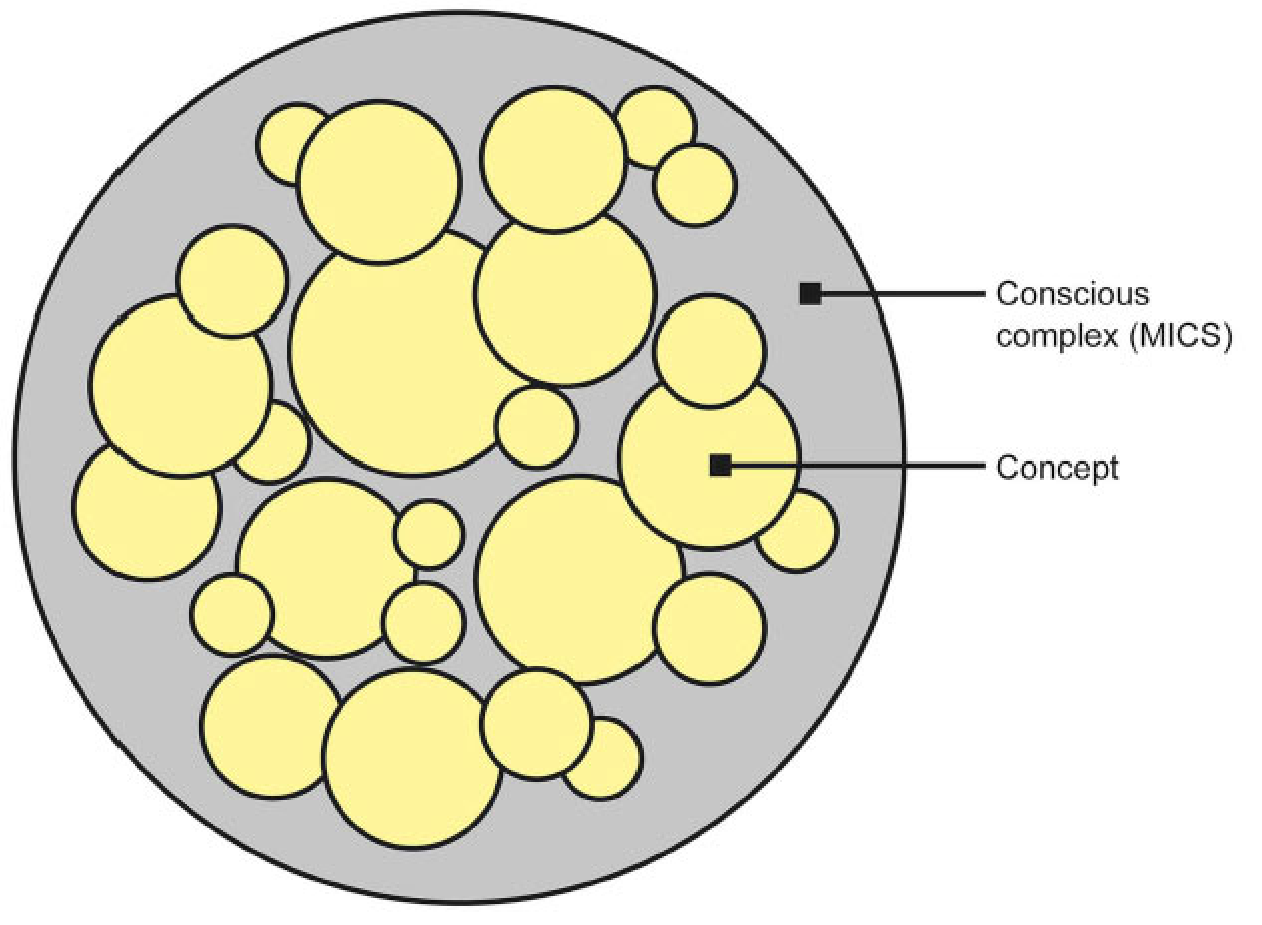

FIGURE 4 - The unified conscious complex (outer gray circle) is formed from a constellation of concepts (yellow circles). The degree to which each concept is present in the experience is quantified by φ (represented by the size of the circle), and the overall quantity of consciousness is quantified by Φ (represented by the size of the gray circle).

The Psychedelic State and IIT

IIT defines conscious experiences as a shape in qualia space. This applies to all conscious states, including the psychedelic state. To appreciate how IIT can provide an explanation for many phenomenological features of the psychedelic state, the following discussion will be separated into three sections. Firstly, using IIT and results from functional neuroimaging data, the effect of psychedelic drugs on neural differentiation (i.e., information) will be examined. Secondly, the effect of psychedelic drugs on neural integration will be addressed. Finally, experiments to test whether the psychedelic state is a state of increased consciousness (integrated information, Φ) will be suggested, together with predictions as to their outcome.

The Effect of Psychedelic Drugs on Information

Functional neuroimaging data and its analysis support the proposal that psychedelic drugs increase the entropy of the brain (Carhart-Harris *et al.*, 2014), producing a state of unconstrained cognition. More detailed analysis of this data revealed an increase in the repertoire of states explored by the brain, consistent with an increase in neural entropy (Tagliazucchi *et al.*, 2014). From the perspective of IIT, both of these observations can be further elucidated, both at the level of the mechanism (concept) and at the level of the conceptual structure (complex).

Before discussing the effect of psychedelic drugs at the level of the concept, it is important to clarify exactly how information is defined within IIT. It is erroneous, from the perspective of IIT at least, to equate the size of a system's state repertoire (i.e., the number of states it can potentially occupy) with the information it generates. Although a large repertoire of states is necessary for a system to generate a large amount of information, it is not sufficient. Stated equivalently, increasing the size of the state repertoire does not necessarily imply an increase in information as defined by IIT. The amount of cause-effect information generated by a mechanism depends on the number of past and future states it *rules out* by entering its current state. Simply adding noise to a system by, for example, allowing neural elements to be randomly activated, will increase the state repertoire but will not increase information. This is because the current state of the system is unable to *constrain* random past or future states. Equivalently, the current state gives no information about those states that had no causal effect on it, nor about randomly generated future states.

Any IIT derived model of the psychedelic state must account for the increase in entropy and size of the state repertoire explored by the brain. In fact, this functional imaging data can be regarded as axiomatic and used as a foundation upon which to develop an IIT-based model of the psychedelic state. As IIT constructs conscious experience as a system of concepts, it makes most sense to begin at the level of the mechanism and then move to the level of the conceptual structure (complex).

When a mechanism enters a specific state, the cause and effect repertoires of system states are specified as distributions with lower entropy than the corresponding unconstrained past and future repertoires. The cause-effect information generated by the mechanism entering the current state is the minimum distance between these repertoires, as explained earlier. This provides a measure of how much the mechanism constrains past and future states of the system. The functional imaging data described earlier revealed that, post-psilocybin, the brain explores a larger repertoire of states and in a more random fashion. From the perspective of IIT, this suggests that the brain's past and future states are less constrained by the states of its mechanisms. As will be shown, and in agreement with this imaging data, this is equivalent to stating that the entropy of the cause and effect repertoires is increased. This means that the cause and effect repertoires of the mechanisms in the complex are shifted toward the unconstrained past and future repertoires. Mathematically, this can be modeled by taking a linear combination of the cause repertoire and the unconstrained past repertoire to generate a *psychedelic cause repertoire* (**Figure 5A**). A *psychedelic effect repertoire* can be similarly generated, by taking a linear combination of the effect repertoire and the unconstrained future repertoire. This approach takes into account the repertoire of states available to the system without invoking additional states resulting from random noise, and can be applied to both the cause repertoire and the effect repertoire to generate a *psychedelic cause-effect repertoire* for every mechanism in the complex (Note that this model does not explain *how* neural entropy is increased by psilocybin, but predicts consequences of the entropy increase revealed by functional imaging data).

If the unconstrained repertoire (past or future), U, contains n states, then U can be described as a point within an (n-1)-dimensional n-simplex. The cause or effect repertoire, R, is another point within this simplex and extending a line between R and U generates a range of repertoires moving from R to U, all of them linear combinations of R and U with increasing *U-character*. According to this model, the psychedelic repertoire, R', lies somewhere on this *R-U* line (this is easier to understand using a diagram and is illustrated in **Figure 5B** for a system with only three possible states):

$$R' = (1 - t)\,R + tU$$

where t is the portion of U mixed with R and $0 \leq t \leq 1$. Clearly, if $t = 0$, then $R' = R$, and if $t = 1$, then $R' = U$.

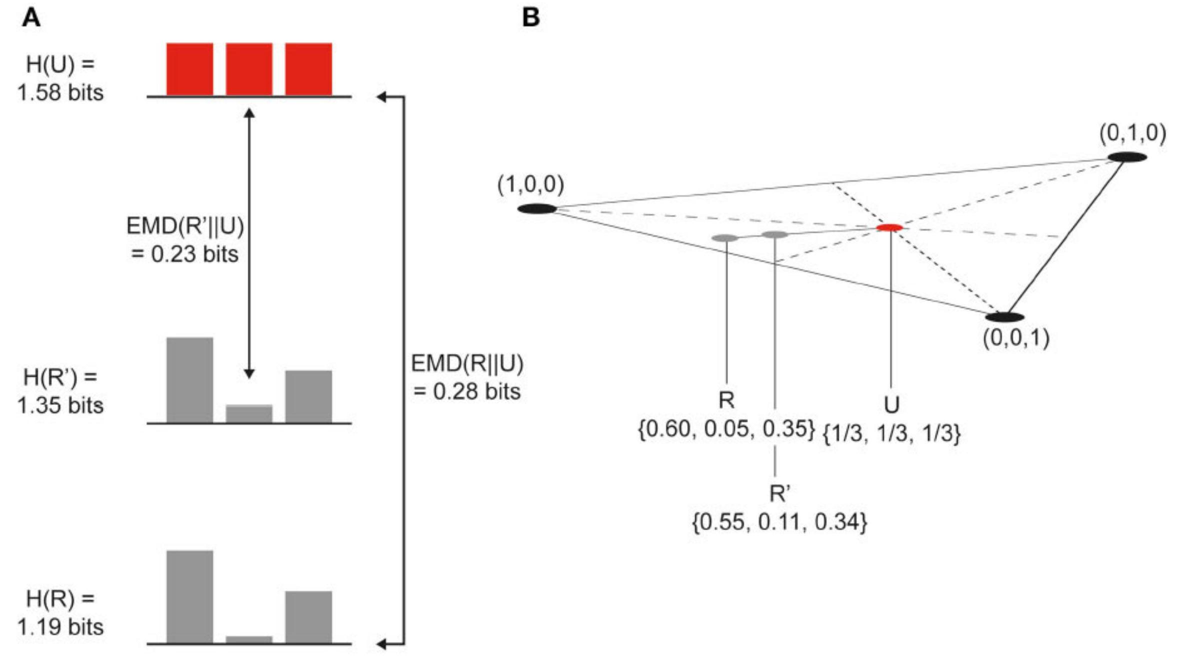

FIGURE 5 - **(A)** Simple 3-state system. A psychedelic (cause/effect) repertoire, R′, is generated using a linear combination of the (cause/effect) repertoire, R, and the unconstrained (past/future) repertoire, U. R′ has a higher entropy than R and is closer to U, generating less (cause/effect) information. **(B)** Each repertoire can be plotted on a 3-simplex. The psychedelic repertoire, R′, lies on a line between the (cause/effect) repertoire and the unconstrained repertoire.

As *U* is, by definition, the maximal entropy distribution, a linear combination of *U* and *R* will always generate a distribution with higher entropy than *R*. Furthermore, in order to move the cause-effect repertoire closer to these maximum entropy distributions, the probabilities of the individual states must be changed, such that formerly high probability states become lower probability and vice versa. Importantly, this is certain to include increasing the probability of certain states from zero or, at least, from a very low probability. In other words, new states would effectively be added to the cause-effect repertoire - the repertoire of potential system states, both past and future, is expanded (actually, the number of states does not increase, but certain states develop a non-zero probability). As this applies to all mechanisms in the complex, the brain would be observed to explore a larger number of states in a more random fashion. This is exactly what is observed in the functional imaging data. From a phenomenological perspective, this has important consequences for the structure of the concept itself. The states within the cause-effect repertoire define what the concept "is about" (Oizumi *et al.*, 2014) and so an expansion of these states essentially changes the nature of the concept and what that concept means to the individual - the psychedelic concept becomes "about more things" or acquires additional characteristics not present in normal consciousness (**Figure 6**). It is interesting to speculate that this might account for the feeling that the world appears somewhat altered in the psychedelic state. Concepts that were once clear and well-defined become novel, strange and perhaps even bizarre or ludicrous.

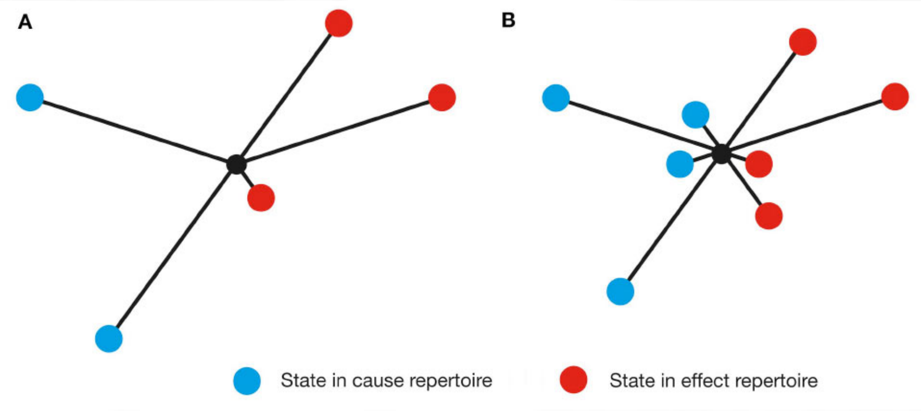

FIGURE 6 - A concept can be visualized by plotting the states of the cause-effect repertoire on a set of arbitrary axes, with the length of each line representing the probability of each state (φ not considered). (A) A concept in a normal waking state. **(B)** A higher-dimensional psychedelic state concept, derived using the linear combination method described in the text.

Further insights are obtained by examining the effect of psychedelic drugs on the cause-effect information specified by each mechanism. The current presentation of IIT uses the Earth Mover's Distance (EMD, aka Wasserstein metric) to measure the distance between the distributions in calculating the cause-effect information (Oizumi *et al.*, 2014). The EMD between the cause or effect repertoire, R, and the unconstrained repertoire, U, can be defined as follows:

If X and Y are random variables with distributions R and U, respectively, and $d(X,Y)$ is a [Euclidean] distance metric, then the infimum of the expectation, E, taken over all possible joint distributions of X and Y (with R and U being the marginal distributions, respectively), gives the EMD:

$$EMD(\mathrm{R}||\mathrm{U}) = inf\,\mathbb{E}[d\ (X, Y)]$$

Let X^* and Y^* be random variables with distributions R and U, respectively, which attain the infimum in the definition of the EMD, then:

$$EMD(\mathrm{R}||\mathrm{U}) = \mathbb{E}[d\ (X^*, Y^*)]$$

R is combined with U using the method described above to generate a new distribution (the psychedelic cause/effect repertoire), R':

$$R' = (1 - t)\ R + tU$$

where $0 \le t \le 1$.

Now, to calculate $EMD(R'||U)$ (i.e., the distance between the psychedelic repertoire, R', and the unconstrained repertoire, U), we must define a new random variable, X', with distribution, R', such that:

$$EMD(R'||\mathrm{U}) = inf\,\mathbb{E}[\mathrm{d}\ (X', Y^*)]$$

where,

$$X' = \begin{cases} X^*, & P(1\text{-}t) \\ Y^*, & P(t) \end{cases}$$

Since $EMD(R'||U)$ is, by definition, the infimum, it must always be the case that:

$$EMD(R'||U) \le \mathbb{E}[d(X', Y^*)]$$

Moreover:

$$\mathbb{E}[d(X', Y^*)] = (1 - t)\ \mathbb{E}[d(X^*, Y^*)] + t\mathbb{E}[d(Y^*,Y^*)]$$

And so, equivalently:

$$EMD(R'||U) \le (1 - t)\ \mathbb{E}[d(X^*, Y^*)] + t\mathbb{E}[d(Y^*, Y^*)]$$

Since, plainly:

$$\mathbb{E}[d(Y^*, Y^*)] = 0$$

This simplifies to:

$$EMD(R'||U) \le (1 - t)\ \mathbb{E}[d(X^*, Y^*)]$$

As defined earlier:

$$EMD(R||U) = \mathbb{E}[d(X^*, Y^*)]$$

So, substituting:

$$EMD(R'||U) \leq (1 - t)\ EMD(R||U)$$

And, since $0 \leq (1 - t) \leq 1$, it follows that:

$$(1 - t)\ EMD(R||U) \leq EMD(R||U)$$

And so:

$$EMD(R'||U) \leq EMD(R||U)$$
